1 Summary

Powdery mildew, caused by the fungus *Blumeria graminis* (DC) Speer, is one of the most important foliar diseases of cereals worldwide. It is an obligate biotrophic parasite, colonising leaf epidermal cells to obtain nutrients from the plant cells without killing them. Syringolin A (sylA), a circular peptide secreted by the phytopathogenic bacterium *Pseudomonas syringae* pv. *syringae*, triggers a hypersensitive cell death reaction (HR) at infection sites when sprayed onto powdery mildew infected wheat which essentially eradicates the fungus. The goal of the present work was to identify genes whose expression was specifically regulated during HR, i.e. genes that might be involved in the switch of compatibility to incompatibility. Microscopic investigations revealed that syringolin inhibits powdery mildew reproduction in both *Arabidopsis* and cereals in a phenotypically similar way. The model plant *Arabidopsis thaliana* provides excellent molecular and genetic resources such as transcriptome analysis by using the *Arabidopsis* full genome microarray. Thus, in a first approach to elucidate the syringolin response in *Arabidopsis*, probes derived from RNA extracted from powdery mildew-infected *Arabidopsis* treated with sylA or control buffer, respectively, were hybridised to microarrays. Additionally, we performed an experiment with uninfected syringolin-treated plants, which do not undergo HR. Surprisingly, the effect of syringolin on the transcriptome of *Arabidopsis thaliana* was dramatically stronger in uninfected plants than in infected plants. Not only were transcript levels of more genes changed in uninfected plants than in infected plants, but transcripts in infected plants accumulated also to a stronger extent in uninfected plants. Detailed analysis of these results lead to the hypothesis that the cellular response to syringolin was negatively controlled by powdery mildew infection in colonised and neighbouring cells at infection sites. The functional annotation of proteins encoded by sylA-affected

transcripts indicated that *sylA* affects gene expression as if mitochondrial function and oxidative phosphorylation were impaired. As a consequence, it seems that plants switch to a fermentative metabolism which could help to avoid overreduction of the mitochondrial ubiquinone pool. The observed *sylA*-induced accumulation of proteasome-related transcripts may reflect an increased demand of proteolytic activity that may help to achieve metabolic changes by selective removal of proteins. The accumulation of transcripts coding for protective proteins may be viewed as a response of the plant to counteract the stress imposed by *sylA*. This lead to a novel hypothesis according to which the HR in infected and syringolin-treated *Arabidopsis* could be the result of the pathogen-induced suppression of gene expression that may lead to insufficient production of protective proteins. Transcript abundance specific for infected tissue could be shown for only few genes and these genes were induced only weakly.

Besides microarray experiments, a second approach for the elucidation of molecular events underlying the occurrence of HR in infected *sylA*-treated plants aimed at the investigation of knock-out mutants harbouring T-DNA insertions in transcripts that accumulated early upon *sylA* treatment and encoded proteins with regulatory functions. The rational was to identify mutants that exhibited insensitivity to syringolin. None of the 11 analysed T-DNA insertion lines exhibited enhanced sporulation efficiency of powdery mildew after syringolin treatment. However, a mutant harbouring a T-DNA insertion in the *At4g12400* gene showed impaired sporulation of the powdery mildew fungus on non-treated leaves. A second mutant line homozygous for an independent T-DNA insertion in the genomic sequence of *At4g12400* revealed a similar phenotype, thus supporting the assumption that non-functionality of the encoded protein indeed negatively affects powdery mildew reproduction in *Arabidopsis*. A homolog of the *At4g12400* gene in soybean encodes

a stress inducible gene whose expression is inducible by heat. We speculate that the At4g12400 encoded protein may exhibit a similar stress-related function and may be necessary to counteract cellular stress imposed on the plant during sporulation. This in turn may be beneficial for the biotrophic fungus which depends on a functional cell metabolism and a living host.

In a third approach for the elucidation of the syringolin response in Arabidopsis, EMS-mutagenised plants were screened for less or no impairment in fungal growth after application of syringolin. Transcriptome analysis of one confirmed mutant revealed elevated levels of ABA-related transcripts without syringolin treatment. We hypothesise that this is associated with elevated endogenous ABA-levels which can lead to a suppression of disease resistance. Moreover, mutant plants exhibited elevated abundance of transcripts encoding stress-related proteins. We assume that enhanced expression of stress-related genes may help to support cell survival, thus preventing HR and supporting powdery mildew growth in infected syringolin-treated mutant plants. This assumption is compatible with the hypothesis developed above, i.e. that a pathogen-induced downregulation of genes encoding stress-related and protective proteins could trigger HR and resistance to powdery mildew in *sylA*-treated wild-type plants. Thus, HR elicited in infected and *sylA*-treated plants appears not to depend on specific regulation of certain genes, but might rather represent the result of pleiotrophic effects caused by syringolin treatment and fungal invasion. The observation that syringolin-induced gene expression exhibited strong similarity to expression patterns induced by the virulent strain of *P. syringae* is intriguing. We hypothesise that *sylA* acts as an effector of *P. syringae* pv. *syringae* that helps to put host plant cells into a physiological state, presumably profitably for the bacteria.

2 Zusammenfassung

Echter Mehltau, verursacht durch den Pilz *Blumeria graminis* (DC) Speer, ist weltweit eine der bekanntesten Blattkrankheiten bei Getreide. Es handelt sich dabei um einen obligat biotrophen Erreger, der die Epidermiszellen befällt und Nährstoffe von der pflanzlichen Zelle bezieht, ohne diese zu töten. Syringolin A (SylA), ein zirkuläres Peptid, das von pflanzenpathogenen Stämmen des Bakteriums *Pseudomonas syringae* pv. *syringae* sezerniert wird, vermag eine „Hypersensitive Reaktion“ (HR) in von Mehltau befallenen Weizenpflanzen zu induzieren und verhindert dadurch eine weitere Ausbreitung des Pilzes. Ziel dieser Arbeit war die Identifizierung HR-regulierter Gene, die an einem Wechsel von Kompatibilität zu Inkompatibilität beteiligt sein könnten. Mikroskopische Untersuchungen ergaben, dass Syringolin die Vermehrung des Mehltapilzes in Arabidopsis und Getreide gleichermassen zu verhindern vermag. Die Modellpflanze *Arabidopsis thaliana* bietet Vorteile bezüglich molekularer und genetischer Forschung, wie z. B. die Untersuchung transkriptioneller Veränderungen mittels des Arabidopsis-Gesamtgenom-Microarrays. In einem ersten Ansatz zur Aufklärung der Syringolinantwort in Arabidopsis wurde RNA aus Blattmaterial von Mehltau befallenen Arabidopsis-Pflanzen nach Syringolinbehandlung bzw. Behandlung mit einer Kontrolllösung isoliert, mit Biotin markiert und anschliessend mit dem Microarray hybridisiert. Des Weiteren wurde ein Experiment mit nicht infizierten und Syringolin-behandelten Pflanzen durchgeführt. Überraschenderweise war die durch Syringolin erzielte Wirkung in nicht infizierten Pflanzen viel stärker als in infizierten Pflanzen. In nicht infizierten Pflanzen veränderte Syringolin die Expressionsstärke von weitaus mehr Genen als in infizierten Pflanzen. Dies führte zu der Annahme, dass eine Infektion mit Mehltau die Antwort von Syringolin in infizierten und benachbarten Zellen negativ beeinflussen kann. Eine

funktionelle Zuordnung der durch Syringolin differenziell exprimierten Produkte deutete an, dass Syringolin direkt oder indirekt mitochondriale Aktivitäten, wie die oxidative Phosphorylierung, negativ beeinflusst. Ein daraus resultierendes Umschalten des pflanzlichen Stoffwechsels hin zu zellulärer Fermentation könnte eine starke Reduktion des mitochondrialen Ubiquinone Pools verhindern. Eine Anreicherung Syringolin-induzierter, proteolytischer Transkripte könnte auf einen erhöhten Bedarf proteolytischer Aktivität in der Zelle hindeuten. Ein selektiver Abbau von Proteinen durch das Proteasom könnte dabei weitreichende Veränderungen im pflanzlichen Metabolismus gewährleisten. Darüber hinaus lässt sich vermuten, dass die erhöhte Anreicherung von Transkripten protektiver Proteine einen Mechanismus der Pflanze darstellt, dem zellulären Stress entgegenzuwirken. Dies führte zur Formulierung einer neuen Hypothese, wonach die HR in infizierten und Syringolin-behandelten Arabidopsis-Pflanzen die Folge einer pathogenabhängigen Unterdrückung der Genexpression darstellen könnte, welches eine unzureichende Synthese protektiver Proteine verursachen könnte. Die Expression nur weniger Gene war spezifisch für infiziertes und Syringolin-behandeltes Gewebe. Darüber hinaus waren diese wenigen Gene nur schwach induziert.

In einem zweiten Ansatz zur Erforschung der molekularen Grundlagen der HR-Auslösung in infizierten SylA-behandelten Pflanzen wurden knock-out-Mutanten, die eine T-DNA in einem Syringolin-induzierbaren Gen trugen, untersucht. Dabei wurden 11 Gene analysiert, deren Expression relativ schnell nach einer Syringolinbehandlung induziert wurde und deren Genprodukte regulatorische Funktionen besitzen. Das Ziel war die Identifizierung Syringolin-insensitiver Mutanten. Keine dieser Pflanzen zeigte jedoch nach Syringolinbehandlung einen dem Wildtyp vergleichbaren Phänotyp. Eine Mutante, die aufgrund einer T-DNA Insertion im At4g12400-Gen isoliert worden war, zeigte an unbehandelten Blättern eine erhöhte

Resistenz gegenüber Befall mit dem echten Mehltaupilz. Dieser Phänotyp konnte durch eine zweite unabhängige Insertion im At4g12400-Gen bestätigt werden. Ein homologes Stress-induzierbares Gen wurde in Sojabohnen identifiziert. Die Expression dieses Gens kann durch Hitze induziert werden. Es ist anzunehmen, dass At4g12400 ebenfalls für ein Protein kodiert, welches durch zellulären Stress, möglicherweise im Zuge pilzlicher Sporulation hervorgerufen, benötigt wird, um diesem entgegenzuwirken. Dies wiederum könnte den biotrophen Erreger, der von einem funktionellen Wertsstoffwechsel abhängt, in der Entwicklung unterstützen.

Ein dritter Ansatz zur Aufklärung der Syringolinantwort in Arabidopsis konzentrierte sich auf die Identifizierung von EMS-mutagenisierten Pflanzen, welche weniger oder gar keine Beeinträchtigung des pilzlichen Wachstums nach einer Syringolinbehandlung zeigten. Dies führte zur Identifizierung einer Mutante. Unbehandeltes Gewebe dieser Mutante wies eine erhöhte Expression von Genen auf, deren Genprodukte eine Rolle in der zellulären Physiologie des pflanzlichen Hormons Abscisinsäure (ABA) spielen. Eine gesteigerte Expression dieser Gene könnte gleichzeitig mit einer erhöhten endogenen ABA-Konzentration einhergehen, was zu einer Unterdrückung der pflanzlichen Abwehr führen kann. Zudem zeigte die Mutante eine erhöhte Expression von Genen, deren kodierten Proteine eine grundsätzliche Funktion während zellulärer Stressreaktionen besitzen. Diese Proteine führen möglicherweise zu einem gesteigerten Schutz sowie dem Überleben der Zelle, was eine Unterdrückung der HR und die erhöhte Anfälligkeit der Mutante gegenüber Mehltau erklären könnte. Diese Annahme unterstützt die anfangs erwähnte Hypothese in dem Sinne, dass die HR eine Folge pathogenabhängiger Unterdrückung der Genexpression darstellen könnte, welche eine unzureichende Synthese protektiver Proteine zur Folge hätte. Demnach scheint das Auftreten der HR in infizierten Syringolin-behandelten Pflanzen eher einen pleiotropen Effekt

darzustellen als eine spezifische Wirkung. Interessanterweise scheint Syringolin das Gen-Expressionsmuster in ähnlicher Weise zu verändern, wie das virulente Stämme des Bakteriums *Pseudomonas syringae* tun. Dies legt die Vermutung nahe, dass SylA als Effektor von *P. syringae* agiert, der hilft, die pflanzliche Wirtszelle in einen für das Bakterium wahrscheinlich profitablen physiologischen Zustand zu bringen.

3 Introduction

Plants are hosts to thousands of infectious diseases caused by a vast array of phytopathogenic bacteria and fungi. A relatively small proportion of potential pathogens is able to successfully invade a specific plant host and cause disease. *Blumeria graminis* (DC.) Speer the causal agent of the powdery mildew disease in cereals is one of the most important foliar diseases worldwide. Powdery mildew is a biotrophic pathogen which requires living host tissue to grow and reproduce. Asexual reproduction starts after landing of a conidial spore on the plant where it exclusively infects epidermal cells. In the course of infection, primary and secondary germ tubes arise from both ends of the conidium. Elongation of the secondary germ tube initiates the differentiation of a swollen appearance referred to as appressorium. The appressorium produces the penetration peg which often successfully penetrates the cell wall and establishes a haustorium. The haustorium which is enclosed by the extrahaustorial matrix and the invaginated host plasma membrane, is responsible for the nutrient transfer from the host plant to the fungus. Successful colonisation by the fungus is followed by the formation of elongated secondary hyphae and the development of conidiophores which produce new conidia. A compatible interaction between wheat and powdery mildew is illustrated in figure 1.1.

Figure 1.1 Colonisation of a wheat epidermal cell by powdery mildew

A conidium (CON) of powdery mildew formed an appressorium (APP) that successfully penetrated a cell transiently expressing *GUS* and formed a haustorium (HAU) and elongating secondary hyphae (ESH). Epiphytic fungal structures were stained with coomassie blue. The picture was taken 40 hours post inoculation. Modified after Schweizer et al., 1999.

Plants have evolved mechanisms to detect and respond effectively to most pathogens. Recognition of a pathogen-derived avirulence factor by a distinct resistance (R) protein in the host plant triggers defense reactions against certain races of biotrophic pathogens. The hallmark of this race-specific resistance is the hypersensitive reaction (HR), a localised cell and tissue death at the site of infection, which prevents further spread of the infection. Although highly effective for the control of many diseases, these R-genes often are not durable because of selection in the pathogen population for variants that overcome the resistance conferred by the R-gene.

The HR can also trigger non-specific resistance throughout the plant, a phenomenon designated as systemic acquired resistance (Ryals et al., 1996). Once triggered, systemic acquired resistance provides resistance to a wide range of pathogens for days. In monocots, this induced resistance is restricted to the site of induction and designated local acquired resistance. In rice, acquired resistance against the rice blast fungus *Pyricularia oryzae* (telomorph: *Magnaporthe grisea*) can be induced by inoculation with the non-host pathogen *Pseudomonas syringae* pv. *syringae* (Smith and Métraux, 1991). Resistance to *Pyricularia oryzae* and defence-related transcript levels can also be increased by application of syringolin, an elicitor that is secreted by the bacteria under appropriate conditions (Wäspi et al., 1998). The function of the syringolins in the interaction of *P. syringae* pv. *syringae* with host plants is currently unknown, however, they represent one of the molecular determinants of *P. syringae* pv. *syringae* by which rice plants can perceive this nonhost pathogen (Hassa et al., 2000; Wäspi et al., 1998).

Syringolins constitute a family of structurally related cyclic peptides designated syringolin A to F. Syringolin A, the major variant present in conditioned media, consists of a 12-membered ring formed by two nonproteinogenic amino acids, 5-methyl-4-amino-2-hexenoic acid and 3,4-dehydrolysine, bound to a valine that in turn is linked to a second valine via an urea moiety (Figure 1.2).

Figure 1.2 Chemical structure of syringolin A

A 12-membered ring structure consisting of 5-methyl-4-amino-2-hexenoic acid and 3,4-dehydrolysine connected to two valines. The valines are connected via an urea moiety. Lines delimit amino acids (Amrein et al., 2004).

Syringolin A (in the following also referred to as syringolin) is synthesised by a non-ribosomal peptide synthetase/polyketide synthetase (Amrein et al., 2004) and its production is controlled by the bacterial *lemA/gacA* two-component regulatory system (Wäspi et al., 1998) necessary for pathogenicity of *Pseudomonas* on host plants (Hrabak and Willis, 1992, 1993). Although syringolin is sufficient to induce resistance and accumulation of defence related transcripts in rice plants, *P. syringae* pv. *syringae* strains and mutants that do not produce syringolin still elicit resistance, indicating that the syringolin perception system in rice is redundant with respect to the resistance response (Reimann et al., 1995; Wäspi et al., 1998).

The effect of syringolin on the interaction of powdery mildew with wheat was reported by Wäspi and co-workers (2001). They could show that application of syringolin to powdery mildew-infected wheat essentially eradicates fungal growth when applied 48 hours after infection. Although these effects of syringolin are reminiscent to certain types of fungicides, syringolin does not exhibit fungitoxic activity against numerous fungi tested such as *Pyricularia oryzae*, *Rhodotorula pilimanae*, *Fusarium graminearum* or *Trichoderma viride* (Wäspi et al., 2001). In contrast to treatment with a fungicide, the curative effect of syringolin on infected wheat was associated with the occurrence of hypersensitive cell death at the infection sites (Wäspi et al., 2001), which correlates with autofluorescence. In addition, autofluorescence indicative for HR is exclusively found in infected cells and no autofluorescence occurs in uninfected tissue (Wäspi et al., 2001). Thus, syringolin was hypothesised to directly or indirectly reprogram colonised host cells to undergo hypersensitive cell death in a compatible interaction. The effect of syringolin on powdery mildew-infected cells leading to autofluorescence and fungal arrest is illustrated in figure 1.3.

Figure 1.3 Induction of HR by application of syringolin on powdery mildew-infected wheat.

Leaves were infected with wheat powdery mildew and sprayed with 40 μ M syringolin 48 hours after infection. Leaves were destained and fungal structures were stained with coomassie blue. Plant-pathogen interactions were photographed under fluorescent (A) and incident light (B), respectively, five days post inoculation (Wäspi et al., 2001).

This thesis shows that a similar curative effect of syringolin is found in powdery mildew-infected *Arabidopsis thaliana*. This offers the possibility to genetically dissect the syringolin response and to use the ATH1 full genome array for transcriptome analysis.

Thus, syringolin treatment or treatment with a control solution was carried out on leaves pre-infected with powdery mildew. In addition, leaf material was collected from uninfected plants that were sprayed with syringolin or the control solution. Subsequent isolation of RNA and hybridisation to the ATH1 gene chip aimed at the identification of genes possibly involved in defence-related HR which might be specifically induced by syringolin treatment of infected *Arabidopsis*.

To address biological functions of genes transcriptionally upregulated by syringolin treatment, T-DNA insertion lines of selected genes were tested for their ability to support powdery mildew growth upon syringolin treatment.

A second approach aimed at the identification of mutants that exhibit less or no impairment on fungal growth after application of syringolin. Screening of EMS-plants revealed one confirmed mutant. This mutant was characterised microscopically and transcriptional changes were investigated by hybridisation to the ATH1 gene chip.

4 Results

4.1 Syringolin A action in powdery mildew-infected *Arabidopsis thaliana*

Syringolin A (referred to as sylA or syringolin for simplicity), one of the molecular determinants secreted by *Pseudomonas syringae* pv. *syringae*, essentially eradicates powdery mildew from infected wheat plants if applied curatively after inoculation (Wäspi et al., 2001). In contrast to treatment with a fungicide, application of syringolin causes autofluorescence, an indication of the hypersensitive reaction (HR). Syringolin-treated cells were unable to undergo plasmolysis and to take up neutral red, indicating irreversible membrane damage of dying cells. So far, the occurrence of sylA-triggered HR has been shown for powdery mildew-infected monocotyledonous plants such as wheat (*Triticum aestivum*) and barley (*Hordeum vulgare*).

With the aim to genetically dissect syringolin action in plants, we analysed the syringolin-response in the model plant *Arabidopsis thaliana*.

4.1.1 Experimental setup and microscopic evaluations

To visualise the effect of sylA on infected *Arabidopsis*, 14-day-old seedlings of *Arabidopsis thaliana* (ecotype Columbia) were infected with a compatible strain of the powdery mildew fungus *Erysiphe cichoracearum* (E.c). The isolate was recovered from *Arabidopsis* and was used throughout this study. Since the growth of *Erysiphe* sp. occurs on the leaf surface, early stages of the infection cycle and disease progression can be easily observed by visual inspection or with microscopic techniques. The disease reaction phenotype in compatible interactions is

characterised by the development of macroscopically visible white, snow-like colonies, which first become apparent on the surface of infected leaves about five days post-inoculation (dpi). Figure 4.1 illustrates microscopic investigations of fungal development at different timepoints.

Figure 4.1 Arabidopsis-powdery mildew interaction

Leaves of 14-day-old *Arabidopsis thaliana* plants were infected with a compatible strain of *Erysiphe cichoracearum*. Leaves were destained by over-night incubation in lacto-phenol solution. Fungal structures were stained with coomassie blue and plant-pathogen interactions were investigated by bright field microscopy. **(A)** 12 hours after infection. The appressorial germ tube (agt) has emerged from the conidium (c). **(B)** 24 hours after infection. A second functional germ tube (sgt) has developed. **(C)** 36 hours after infection. Hyphae (hy) arose from both germ tubes and have elongated by two days post-inoculation **(D)**. Scale bar: 100 μ m.

Twelve hours after infection (hai), an unlobed germ tube, referred to as appressorial germ tube, had arisen from the end of a conidium (Figure 4.1 A). Often, a second germ tube emerged from the opposite end of a conidium within 24 hai (Figure 4.1 B). By 24 hai, most conidia had germinated. The first germ tube could be distinguished from the second by its slightly enlarged and swollen appearance. Because of its distinct morphology, we refer to the first germ tube as the appressorial germ tube. The appressorial germ tube produced a penetration peg, which often successfully penetrated the cell wall and established a haustorium. By 36 hai, hyphae had arisen from both germ tubes (Figure 4.1 C) and had elongated by two dpi (Figure 4.1 D), and started to form a network on the leaf surface. At this timepoint, plants were treated with a control solution (0,05% Tween 20) or a 20 μ M

solution of sylA and leaf material was evaluated under the microscope five dpi, corresponding to 72 hours after treatment (hat). A schematic overview of the experimental setup is illustrated in figure 4.2.

Figure 4.2 Overview of the experimental setup

14-day-old seedlings of *Arabidopsis thaliana* were infected with a compatible strain of *Erysiphe cichoracearum* at timepoint 0 hours (h). At 48 hours after infection (hai), plants were treated with a 20 μ M solution of sylA or a control solution (0,05% TWEEN 20). Leaves were destained and stained for fungal structures five days post inoculation (dpi), corresponding to 72 hours after treatment (hat).

Treatment with a control solution had no effect on fungal reproduction and resulted in a compatible interaction. By 24 hat, elongated hyphae had started to form a network on the leaf surface (Figure 4.3 A). The fungal network became dense 48 hat (Figure 4.3 B). At this timepoint young conidiophores were formed and became numerous 72 hat (Figure 4.3 C). Infected plants sprayed with a control solution emitted no autofluorescence at any timepoint (Figure 4.3 D-F).

Figure 4.3 Arabidopsis-powdery mildew interactions on control-treated leaves

Leaves of 14-day-old *Arabidopsis thaliana* plants were infected and sprayed with a control solution 48 hours after infection. Leaves were destained by over-night incubation in lacto-phenol solution. Fungal structures were stained with coomassie blue and plant-pathogen interactions were photographed under incident and fluorescent light, respectively, 24 (A, D), 48 (B, E) and 72 (C, F) hours after treatment. With the formation of conidiophores (cp) at five days post-inoculation, the fungus has successfully completed its lifecycle. Scale bar: 100 μ m.

When plants were sprayed with a solution of 20 μ M sylA 48 hai, fungal growth was arrested. Thus, no further development and sporulation had occurred by 72 hat (Figure 4.4 A). Tissue collapse and autofluorescence at the sites of infection

was apparent 48 hat and became clearly visible 72 hat (Figure 4.4 B). In rare cases no autofluorescence became apparent at the infection sites which was accompanied with a progression of fungal growth. In general, arrest of fungal growth was associated with autofluorescence at 100% of infection sites. Spraying of 20 μ M sylA on uninfected plants had no visible effect, neither by eye nor by bright field (Figure 4.4 C) and epifluorescence microscopy (Figure 4.4 D). Killing of the powdery mildew fungus with a fungicide resulted in an arrest of fungal growth (Figure 4.4 E). However, in contrast to a treatment with sylA, no autofluorescence became visible at 88% of infection sites (Figure 4.4 F).

Figure 4.4 Effect of syringolin A on powdery mildew-infected and uninfected *Arabidopsis* leaves

Infected leaves of *Arabidopsis thaliana* were treated with sylA 48 hours after infection. Seventy-two hours after treatment, leaves were destained by over-night incubation in lacto-phenol solution. Fungal structures were stained with coomassie blue and plant-pathogen interactions were photographed under incident (A) and fluorescent light (B) to visualise cells emitting autofluorescence as indicated by arrows (AF). In uninfected tissue (C) treated with sylA, no autofluorescence was visible 72 hat (D). If plants were infected and treated with a fungicide 48 hours after infection (E), arrest in fungal growth was not correlated with the occurrence of autofluorescence (F). Scale bar: 100 μ m.

Powdery mildew penetrates only into the epidermal cells where it forms specialised food absorptive structures called haustoria. Application of syringolin on wheat plants two days after infection with a virulent strain of powdery mildew triggers the accumulation of autofluorescing material specifically in the epidermis (Wäspi et al., 2001). Figure 4.5 illustrates that in infected *sylA*-treated *Arabidopsis* autofluorescence was relatively weak in epidermal cells, although clearly visible against a dark background as indicated by arrowheads (eAF). However, autofluorescence was much stronger in mesophyll cells underlying the infection sites (mAF) as indicated by arrows (Figure 4.5).

Figure 4.5 Autofluorescence at infection sites on leaves treated with *sylA*

Infected leaves of *Arabidopsis thaliana* were treated with *sylA* 48 hours after infection and were photographed under fluorescent light 72 hat. Cells emitted autofluorescence at infection sites. Accumulation of autofluorescing material was weak in epidermal cells (eAF) but clearly visible in the mesophyll cell layer (mAF). Scale bar: 100 μm .

Phytotoxic effects such as yellowing of leaves only became apparent after spraying 40 to 100 μM or higher concentrations of *sylA* (data not shown). Thus, spray application of a 20 μM *sylA* solution on powdery mildew-infected *Arabidopsis* plants converted a compatible interaction into an incompatible one, similar to the effects observed after *sylA* treatment of powdery mildew-infected wheat (Wäspi et al., 2001).

4.1.2 Transcriptional analysis of the *sylA* response using ATH1 gene chips

4.1.2.1 Differential expression patterns in *sylA*-treated plants

To understand the molecular events underlying the conversion of compatibility to incompatibility exerted by *sylA*, a series of Affymetrix gene chip hybridisation experiments was performed. The aim was to identify genes possibly involved in the switch between compatibility to incompatibility that is exerted by *sylA*, such as genes activated or repressed after *sylA* treatment of powdery mildew-infected plants, but not by *sylA* treatment of uninfected plants. Thus, 14-day-old *Arabidopsis thaliana* plants were inoculated with *Erysiphe cichoracearum* by tapping highly infected *Arabidopsis* leaves on the leaf surface of experimental plants. This resulted in a high infection density (~ 200 spores/mm², see section Materials and Methods, chapter 6.3.1). After 48 hours, plants were sprayed with a 20 μ M solution of *sylA* or a control buffer solution. RNA was extracted from the plants at 0.5, 1, 2, 4, 8, and 12 hat. Equal amounts of plant material were pooled in pairs, resulting in an early pool, referred to as IS1 for infected *sylA*-treated plants and sample collection at 0.5-1 hat. A middle pool was obtained from infected and *sylA*-treated plants collected at 2-4 hat (IS4) and a late RNA pool of plant material collected at 8-12 hat (IS12). The experimental procedure is illustrated in figure 4.6.

Figure 4.6 Illustration of setup for gene chip hybridisation experiments

Leaves of 14-day-old *Arabidopsis thaliana* seedlings were first infected with a compatible strain of *Erysiphe cichoracearum*. Second, plants were treated with sylA or a control solution 48 hours after infection. Third, total RNA was extracted from leaves collected at six different time points. Starting material for gene chip hybridisation experiments was obtained by combining plant material derived from the two early, two middle, and the two late time points at a ratio of 1:1 (w/w). h: hours

In addition, leaf material was collected at one hat (S1) and at 8-12 hat (S12) from uninfected plants that were sprayed with 20 μ M sylA or the control solution. Total RNA was extracted from the plants, labelled and hybridised to Affymetrix ATH1 gene chips representing the complete *Arabidopsis* genome. An overview of the experiments undertaken is given in table 4.1.

Table 4.1 Overview of gene chip hybridisation experiments

Experiments	Infection	Treatment	Sample collection
IS1	<i>E. cichoracearum</i>	control solution vs. syringolin [20 µM]	0,5-1hat ²
IS4	<i>E. cichoracearum</i>	control solution vs. syringolin [20 µM]	2-4 hat
IS12	<i>E. cichoracearum</i>	control solution vs. syringolin [20 µM]	8-12 hat
S1	-	control solution vs. syringolin [20 µM]	1 hat
S12	-	control solution vs. syringolin [20 µM]	8-12 hat
I60 ¹	uninfected vs. infected plants	control solution	56-60 hai ³

- (1) The effect of infection (I) on transcript abundance was calculated by comparing expression ratios derived from uninfected plants versus infected plants, both treated with a control solution. The timepoint of sample collection corresponded to 56-60 (60) hours after infection (48 hai + 8-12 hat).
- (2) Hours after treatment.
- (3) Hours after infection.

All experiments were repeated three times independently. Stringent criteria for data analysis were used. The ratios of signal intensities corresponding to treated and control-treated samples (t/c-ratio) were calculated. For statistical analysis, the parametric test using all available error estimates as implemented in the Genespring software (see section Materials and Methods, chapter 6.8.2) was chosen. Furthermore, genes were considered statistically significant if they passed the multiple test correction (MTC) according to Benjamini and Hochberg (Benjamini and Hochberg, 1995). The results in terms of numbers of transcripts whose levels were altered significantly more than 2-fold and 3-fold are presented in table 4.2.

Table 4.2 Numbers of differentially expressed transcripts

Experiments	t/c ratio ^{1,2}			
	≥ 2	$\leq 0,5$	≥ 3	$\leq 0,333$
IS1	0	0 [1]	0	0
IS4	0 [68]	0 [4]	0 [25]	0 [1]
IS12	455 [621]	0 [482]	215 [264]	0 [51]
S1	19	28	1	4
S12	2394	2873	1121	1760
I60	1045	996	555	275

- (1) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$) including multiple test correction (MTC).
- (2) Values in brackets designate genes that obtained a p-value ≤ 0.05 but that have not passed the MTC.

Surprisingly, in experiments IS1 and IS4 (plant material collected 0,5-1 hat and 2-4 hat, respectively) the expression of no gene was reproducibly altered more than 2-fold in all three biological independent repetitions. In experiment IS1, only one gene, coding for a germin-like protein 3 (At5g20630), was significantly repressed (t/c ratio: 0,4) as judged by Welch's t-test statistics (p -value ≤ 0.05) when MTC was excluded (Table 4.2). Likewise, no gene has passed the multiple test correction in experiment IS4, but among transcripts that obtained p-values ≤ 0.05 , four genes whose expression was lowered more than 2-fold were identified when MTC was excluded and 68 transcripts showed at least a 2-fold increase in abundance.

In IS12, 455 and 215 genes that passed all statistical tests were upregulated 2-fold and 3-fold, respectively, whereas no gene downregulated by sylA treatment passed the multiple test correction. The distributions of the t/c ratios of upregulated genes in experiments IS4, IS12 and S12 are shown in a Venn diagram in figure 4.7.

Figure 4.7 Overlap between genes upregulated more than 2-fold in infected and uninfected plants treated with *sylA*

The Venn diagram represents the distribution of significantly upregulated genes ($p\text{-value} \leq 0.05$, MTC) in experiments IS12 and S12. Multiple test correction was not applied to genes upregulated in experiment IS4.

Two genes (which did not pass the MTC) were exclusively upregulated in experiment IS4. These genes encoded a mitochondrial pentatricopeptide (PPR) repeat-containing protein (At3g61170) and a zinc finger family protein (At2g24830). To our surprise, all except 13 of the 455 genes which were more than 2-fold upregulated at the 8-12 hat timepoint (IS12) in infected tissue were also included in the set of genes activated when *sylA* was sprayed on uninfected plants (S12). A list of the 13 genes exclusively present in experiment IS12 is given in table 4.3. It includes genes encoding proteins responding to biotic (Table 4.3, At2g34930, row #1) and abiotic stimuli (Table 4.3, At1g29410, row #10), as well as genes encoding proteins involved in the regulation of transcription (Table 4.3, At2g35340, At5g13080, rows #12, 13). Further genes encoded proteins of unknown biological functions.

RESULTS

Table 4.3 Expression patterns of genes exclusively upregulated by sylA in infected tissue

Row	Description	Locus ¹	Protein	t/c ratio ² IS12
1	disease resistance family protein (contains LRR domain)	At2g34930	-	2,9
2	expressed protein	At1g49930	-	2,3
3	expressed protein	At3g04630	WDL1	3,5
4	expressed protein	At3g51500	-	2,1
5	expressed protein	At4g22960	-	2,6
6	expressed protein	At5g44990	-	2,8
7	expressed protein	At5g47050	-	2,2
8	expressed protein	At5g63220	-	2,1

11	putative heterogeneous nuclear ribonucleoprotein	At5g47620	-	2,2
12	putative RNA helicase	At2g35340	-	2,9
13	WRKY family transcription factor	At5g13080	WRKY75	2,3

- (1) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>).
- (2) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$) and MTC.

Moreover, transcripts that exhibited higher expression in experiment IS12 compared to experiment S12 might also represent genes that were possibly involved in the induction of HR, which exclusively occurs in infected tissue treated with sylA. Among genes whose transcript levels were altered more than 2-fold by sylA in infected plants (IS12), eighteen genes exhibited higher expression in experiment IS12 compared to the expression of corresponding genes in experiment S12. Significance of difference between t/c ratios of these 18 genes in experiments IS12 and S12 was judged by Student's t-test statistics ($p\text{-value} \leq 0.05$). This revealed only one gene encoding an expressed protein (At5g14730) whose t/c ratio in experiment IS12 was significantly higher as compared to the corresponding t/c ratio in experiment S12. A list of the 18 genes and the corresponding p-values is given in table 8.1 (Appendix B). Thus, very few genes were identified that were differentially regulated by sylA application on infected plants, which results in HR, as compared to sylA treatment of uninfected plants, which develop no visible symptoms. In addition, these few genes were induced only weakly.

4.1.2.2 Transcript accumulation following powdery mildew infection

The effect of infection alone on transcript abundance was calculated by comparing expression ratios derived from uninfected and infected plants that were both treated with a control solution. Plant material was collected 8-12 hat corresponding to 56-60 hours after infection (I60, Table 4.1).

The venn diagram in figure 4.8 A represents the overlap between genes which were more than 2-fold upregulated in infected (IS12) and uninfected (S12) plants treated with sylA, and genes exhibiting more than 2-fold elevated expression after fungal infection alone (I60). Of the 1045 (570 + 400 + 74 + 1) genes which were more than 2-fold upregulated in infected plants (I60), 474 genes (400 + 74) were also induced more than 2-fold by sylA in uninfected tissue and 75 genes (74 + 1) were superinduced by sylA treatment of infected plants.

Figure 4.8 Overlap of sylA and powdery mildew-responsive gene expression

The venn diagram represents the distribution of significantly ($p\text{-value} \leq 0.05$, MTC) upregulated (A) and downregulated (B) genes in experiments I60, IS12 and S12.

None of the genes upregulated by powdery mildew alone was repressed significantly by *sylA* in experiment IS12, but 60 of these genes were downregulated more than 2-fold by *sylA* in uninfected tissue in experiment S12 (data not shown in the venn diagram). A list of these genes and their corresponding t/c ratios is given in table 8.2 (Appendix C). Among others, these genes included transcripts involved in cellular transport processes (Table 8.2, rows #4ff) as well as transcripts encoding proteins involved in abiotic and biotic stress response, e.g. disease resistance proteins (Table 8.2, rows #17ff), a glucanase (Table 8.2, At3g57240, row #16), a protein involved in jasmonic acid biosynthesis (Table 8.2, At1g17990, row #21), and a member of the seven-transmembrane-MLO family (Table 8.2, At3g45290, row #25). Moreover, several genes present in the category 'protein metabolism' encoded proteins exhibiting kinase activity (Table 8.2, rows #32ff).

Figure 4.8 B represents a comparison of genes whose expression was more than 2-fold downregulated in experiments IS12, S12 and I60. Of the 996 (688 + 308) genes whose corresponding transcript levels were lowered by the fungus (I60), 688 were also downregulated by *sylA* in uninfected tissue. Among genes upregulated by *sylA* in infected tissue, the expression of three genes was lowered by fungal infection (not shown in venn diagram), as represented in table 4.4. These genes encoded a disease resistance family protein containing a leucine-rich repeat-domain (Table 4.4, At2g34930, row #1) that was exclusively present in experiment IS12, whereas a mitochondrial internal NAD(P)H dehydrogenase (Table 4.4, At1g07180, row #2) involved in electron transfer, and a MATE efflux protein (Table 4.4, At1g15180, row #3) exhibiting drug transporter activity, were similarly upregulated in uninfected tissue by *sylA* (S12). In addition, six genes whose transcription levels were repressed by the fungus were not included in experiment IS12. However, these genes were more than 2-fold upregulated in experiment S12 where syringolin was applied on uninfected plants. The corresponding t/c ratios of these genes are presented in table 4.4.

Table 4.4 Expression patterns of genes upregulated by sylA in infected and/or uninfected plants and downregulated by fungal infection alone

Row	Description	Locus ¹	Protein	t/c ratio ^{2,3}		
				I60	IS12	S12
1	disease resistance family protein (contains LRR-domain)	At2g34930		0,3	2,9	-
2	internal NAD(P)H dehydrogenase	At1g07180	NDA1	0,4	4,2	5,6
3	MATE efflux family protein	At1g15180		0,3	8,9	4,2
4	SEC14 cytosolic factor family protein	At1g30690		0,4	-	2,6
5	expressed protein	At4g33666		0,5	-	2,3
6	U3 ribonucleoprotein (Utp) family protein	At5g08600		0,4	-	2,9
7	elongation factor 1B alpha-subunit 1	At5g12110		0,3	-	2,1
8	expressed protein	At5g24570		0,4	-	3,8
9	PRT1 protein	At3g24800	PRT1	0,5	-	2

- (1) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>).
- (2) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$) and MTC.
- (3) Dashes designate genes that have not passed the Welch's t-test and MTC.

Surprisingly, sylA application on uninfected plants appeared to have a much higher impact on the transcriptome than application on infected plants: 2394 genes were activated more than 2-fold and of 2873 genes the transcript levels were lowered more than 2-fold by sylA treatment of uninfected plants, as compared to 455 activated and 0 repressed genes when sylA application occurred on infected plants (Table 4.2). Thus, in uninfected plants syringolin changed the expression of more genes than in infected plants. This result can be explained partly by the fact that the transcript level ratios of 368 genes activated more than 2-fold in both experiments IS12 and S12, but not in I60 (Figure 4.8 A), was almost always lower in experiment IS12 (sylA on infected plants) than in experiment S12 (sylA on uninfected plants). The average of IS12/S12 over these genes is $0,57 \pm 0,2$, significantly different from 1 (p -value < 0.001 ; one sample t-test). For only 22 genes is this ratio larger than 1.

There is no indication that this is generally caused by a small induction of these genes by the fungus alone and thus would represent an artefact caused by the chosen cut-off value of 2, because the average of IS12 x I60/S12 over these 368 genes is $0,68 \pm 0,3$, significantly different from 1 (p-value < 0.001). The corresponding value over all 1920 (1552 + 368) genes activated by sylA alone (S12) but not the fungus alone (I60) is $0,69 \pm 0,2$ (p-value < 0.001). In contrast, this value over the 75 genes that were activated in experiments IS12 and I60 is $1,08 \pm 0,6$, which is not significantly different from 1 (p-value > 0.5). Similar relations hold true for genes with t/c ratios $\leq 0,5$.

In conclusion, it appears that in infected plants, sylA indeed changed the activity of fewer genes to a lesser extent than in uninfected plants.

These results on the transcriptional changes obtained in infected sylA-treated plants do not allow any conclusion on a hypothesised HR specific regulation of certain genes.

4.1.2.3 Characteristics of transcriptome changes exerted by syringolin application

As described above, the ability of syringolin to selectively induce HR on *E. cichoracearum*-infected plants was found not to be correlated with transcriptional upregulation of putative HR-related genes. However, plants were found to strongly respond to syla treatment by altering transcription of genes covering a broad range of biological functions. These transcripts were grouped according to biological function GO (Gene Ontology) terms (<http://www.arabidopsis.org/tools/bulk/go/>). The distributions of biological function GO terms for genes exhibiting t/c ratios altered more than 2-fold upon syla treatment of infected and uninfected tissue are illustrated in pie diagrams (Figure 4.9).

As evident from figure 4.9, in powdery mildew-infected plants (Figure 4.9 A) the distribution of syla-induced genes with regard to functional categories was similar to the one found for genes whose expression was induced by syla treatment of uninfected plants (Figure 4.9 B), although, the number of genes was larger. In uninfected plants the distribution of upregulated genes (Figure 4.9 B) was also similar to the one of downregulated genes (Figure 4.9 C). Unexpectedly, more genes were downregulated than upregulated as previously illustrated in terms of numbers in table 4.2.

Figure 4.9 Pie-graph illustrating proportions of functional groups involved in the syringolin A response in infected and uninfected tissue

Classification of *sylA*-responsive genes exhibiting t/c ratios greater than two in infected (A) and uninfected plants (B) and smaller than 0,5 in uninfected tissue (C) 8-12 hat according to biological function GO terms. The corresponding web page can be retrieved by entering the locus identifier on the TAIR web page (<http://www.arabidopsis.org/tools/bulk/go/>). It should be noted that one gene can have more than one annotated function.

Since syringolin exerted dramatic transcriptional changes when applied on uninfected tissue, the increased or decreased transcript levels where analysed in order to understand the effect of syringolin in uninfected *Arabidopsis* in general. As seen before, this set of genes included almost all transcripts that were also activated by *sylA* in infected plants.

In order to decrease the large number of genes significantly altered by sylA application on uninfected plants and for facility of inspection of the data, the cut-off for t/c ratios was set to 3 and 0,333, respectively. Transcripts that accumulated in infected and uninfected plants upon sylA treatment were categorised according to functional pathways as represented in the MAPMAN software (Thimm et al., 2004) and are listed in table 8.3 (Appendix D). In the following, prominent groups of genes are presented in separate tables and figures.

The highest proportion of genes belonged to the functional categories of metabolic processes (including genes involved in physiological, biological and cellular processes, according to TAIR function GO terms), protein metabolism, and to genes that were not linked to any biological process so far.

Figure 4.10 presents an overview of all genes encoding proteins involved in various metabolic processes whose expression was altered by syringolin. Concerning carbohydrate metabolism, syringolin reduced transcript levels of genes encoding enzymes involved in synthesis and degradation of starch (Table 8.3, rows #136ff, 152ff). Similarly, the synthesis of sucrose was inhibited (Table 8.3, rows #147ff) but three genes encoding enzymes involved in sucrose degradation exhibited elevated expression ratios (Table 8.3, rows #164ff). In addition, sylA generally lowered transcript abundances corresponding to enzymes functioning in secondary, lipid, amino acid, sulphate and nucleotide metabolism (Figure 4.10).

Figure 4.10 Alteration of transcript abundance of genes encoding metabolic proteins

Syringolin application on *Arabidopsis* alters the expression of genes encoding proteins involved in different metabolic processes (X-axis). The Y-axis represents the number of genes whose expression was enhanced (filled column elements) or lowered more than 3-fold (open column elements) in each category.

Among genes encoding proteins involved in cell wall metabolism the majority exhibited t/c ratios lower than 0,333 and predominantly encompassed genes encoding cell wall modifying and degrading proteins (Table 8.3, rows #59ff, 110ff), but also cell wall proteins and proteins related to the synthesis of the cell wall (Table 8.3, rows #1ff, 33ff, 44ff).

Genes encoding proteins with a function in plant primary metabolism included enzymes involved in glycolysis and the tricarboxylic acid cycle as well as proteins that are involved in fermentation. Corresponding expression values of these genes in infected (IS4, IS12) and uninfected plants (S12) treated with sylA are given in table 4.5.

Table 4.5 Differentially expressed genes of infected and uninfected plants treated with syIA involved in glycolysis, tricarboxylic acid cycle and fermentation

26	putative pyruvate decarboxylase (PDC1)	At4g33070	24,8	241	656,6

- (1) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>).
- (2) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$). Dashes designate genes that have not passed the Welch's t-test.
- (3) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$) and MTC. Dashes designate genes that have not passed the Welch's t-test and MTC.

These data revealed that more genes encoding glycolytic enzymes were upregulated by syIA than downregulated, suggesting that syringolin might lead to an induction of sucrose breakdown via glycolysis (Table 4.5, rows #13ff). However, the expression of only few genes encoding enzymes of the tricarboxylic acid cycle (Table 4.5, rows #22, 23) was altered by syIA. Enzymes with a function in cellular

fermentation encompassed a lactate dehydrogenase (Table 4.5, At4g17260, row #25) and a pyruvate decarboxylase (Table 4.5, At4g33070, row #26).

With regard to primary metabolism, it is striking that the expression of genes encoding proteins involved in photosynthetic activity were strongly inhibited upon sylA treatment (Table 8.3, rows #422ff). In contrast, genes encoding proteins functioning in mitochondrial processes were induced by syringolin (Table 4.6).

Table 4.6 Differentially expressed genes of infected an uninfected plants treated with sylA involved in mitochondrial electron flow

Row	Description	Protein	Locus ¹	t/c ratio		
				IS4 ²	IS12 ³	S12 ³
1	alternative oxidase 1a, mitochondrial	AOX1A	At3g22370	-	2,3	8,6

8	internal NAD(P)H dehydrogenase in mitochondria	NDB2	At1g07180	-	4,2	5,6

- (1) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>).
- (2) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$). Dashes designate genes that have not passed the Welch's t-test.
- (3) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$) and MTC. Dashes designate genes that have not passed the Welch's t-test and MTC.

Among genes whose encoded proteins were related to the mitochondrial electron transport, several were upregulated upon sylA treatment, such as genes encoding an external and internal NAD(P)H dehydrogenase (Table 4.6, At2g20800, At1g07180, rows #7, 8). In addition, this also included genes encoding subunits of the alternative oxidase (Table 4.6, At3g22370, At3g22360, At1g32350, rows #1ff),

an enzyme providing a branching point that directs mitochondrial electron flow via an alternative pathway.

Moreover, we identified two genes encoding a stomatin-like protein and a putative prohibitin (Table 8.3, At5g54100, At3g27280, rows #546, 547). These proteins belong to the superfamily of PID (Proliferation, Ion, and Death) proteins also described as band 7 proteins identified in maize which have been associated with hypersensitive reactions involving cell death and pathogen resistance (Nadimpalli et al., 2000). Further genes encoding members of the PID gene family were classified to the category of protein metabolism (Table 8.3, rows #548ff).

A high number of genes encoding proteins involved in cellular degradation processes was found in the functional group of protein metabolism. Proteins related to this category were predominantly identified as subunits of the 26S proteasome core and lid particles including components of the ubiquitination multi-enzymatic system (Table 4.7). Many of the Arabidopsis subunits are encoded by at least a pair of paralogs. Amino acid sequence identity among the paralogs is high (>90%) suggesting that the family members are functionally redundant. The existence of these conserved paralogs in Arabidopsis may simply reflect the absolute requirement for expression of these gene products across a wide range of developmental states and environmental conditions.

RESULTS

- (1) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>).
- (2) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$). Dashes designate genes that have not passed the Welch's t-test.
- (3) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$) and MTC. Dashes designate genes that have not passed the Welch's t-test and MTC.

Representatives of all 20S core protease (CP) subunits and of all 19S regulatory particles (RP) were found among genes upregulated by sylA, several were represented by pairs. Transcripts that accumulated already 2-4 hat were identified among RP and CP subunits. All except subunit RPN 9a (Table 4.7, At5g45620, row #31) were transcriptionally induced in infected and uninfected plants treated with sylA, however expression values in uninfected plants were always higher.

The functional category of genes related to development encompassed subunits of the COP9 signalosome (CSN). Representatives of the eight subunits composing the CSN were upregulated more than 2-fold by sylA in uninfected plants and three subunits were also identified among genes upregulated in infected plants upon sylA treatment (Table 4.8, At5g14250, At5g42970, At5g56280). The CSN shares a strong similarity to subunits of the lid complex of the 26S proteasome and has been discussed as a specialised proteasome regulator (Schwechheimer and Deng, 2001). Differentially expressed genes encoding subunits of the CSN and the corresponding lid paralogs are given in table 4.8.

Table 4.8 Differentially expressed genes of infected an uninfected plants treated with sylA encoding members the COP9 signalosome

Furthermore, several components of the SCF (Skp1/Cullin/E-box protein)-type E3 ligase complex were transcriptionally induced by sylA, such as ASK1 (Table 8.3, At2g25700, row #583), the Arabidopsis homolog of SKP1 (S-phase Kinase-associated Protein), and many F-box proteins (Table 8.3, rows #557ff). Further genes encoded members of the AAA (ATPases Associated with different Activities)-type ATPase family responsible for protein-unfolding or dissociation of protein-protein interactions (Table 8.3, rows #524ff).

In addition, we identified a high number of proteins with predicted kinase activity (according to molecular function GO terms), including receptor-like kinases (RLKs) with various extracellular domains (specified in squared brackets in table 8.3, rows #680ff.). Figure 4.11 illustrates sylA-dependent alteration of transcript abundances of genes encoding RLKs categorised into groups according to their extracellular domains.

Figure 4.11 SylA-dependent alteration of transcript abundance of genes encoding receptor-like kinases

Syringolin application on Arabidopsis alters the expression of genes encoding RLKs. The X-axis represents groups of RLKs classified according to their extracellular domains. The Y-axis represents the number of genes whose expression was enhanced (filled column elements) or lowered more than 3-fold (open column elements). Abbreviations for the extracellular domains: DUF26, domain of unknown function 26; K, kinase; LEC, legume lectin; LRR, leucine-rich repeat; SD, S-locus glycoprotein-like domain; TK, transmembrane/kinase; WAKL, wall-associated kinase like.

Further proteins with a role in cellular regulative processes included GTP-binding proteins (Table 8.3, rows #844ff) and proteins involved in calcium signalling (Table 8.3, rows #863ff). Corresponding transcripts accumulated upon sylA treatment in infected and uninfected tissue.

Genes that were classified to the group of proteins responding to abiotic and biotic stimuli included many members of the heat shock protein (Hsp) family. An overview of all Hsps present in experiments IS4, IS12 and S12 is given in table 4.9. Of the five major families of Hsps present in infected plants treated with sylA, we identified members of the Hsp70 family together with their co-chaperones (e.g. DnaJ and GrpE), of the Hsp100 family, and several members of the family of small Hsps (Table 4.9). Six of the twelve Hsps present in experiment IS12 also exhibited elevated expression in experiment IS4 where plant material was collected 2-4 hat. All Hsps present in experiments IS4 and IS12 were also included in the set of 3-fold differentially expressed genes in uninfected plants treated with sylA (S12).

Several genes encoding members of the small Hsp family upregulated in experiments IS4 and IS12 were identified as cytosolic class-I (C-I) (Table 4.9, At3g46230, At1g59860, At2g29500, At1g53540, rows #13, 15ff) and class-II (C-II) small Hsps (Table 4.9, At5g12020, At5g12030, rows #14, 18). Two genes encoded mitochondrial (M) small Hsps (Table 4.9, At5g51440, At4g25200, rows #19, 20), both were already upregulated in infected tissue 2-4 hat and one of them (Table 4.9, At5g51440, row #19) exhibited highest expression values among all Hsp genes upregulated by sylA in infected and uninfected plants. Further mitochondrial Hsps transcriptionally induced by sylA included two members of the Hsp70 family (Table 4.9, At4g37910, At5g55200, rows #7, 8), and a chaperonin (Table 4.9, At3g23990, row #1) which belongs to the Hsp60 protein family.

One of the early induced Hsp genes (IS4) was *Hsp81-1* (Table 4.9, At5g52640, row #9), one of the six members belonging to the Arabidopsis Hsp90 family (80-90 kDa). Proteins of the Arabidopsis Hsp90 family exhibit significant similarities to Hsp90 proteins from other organism for which an active role in signal transduction has been reported (Picard et al., 1990). Whether the function of Hsp90 proteins in Arabidopsis is analogous to that of Hsp90 proteins in other systems remains to be determined. Interestingly, three genes encoding Hsps localised in plastids (P) were downregulated by syringolin in uninfected plants (Table 4.9, At1g26230, At4g21870, At5g57710, rows #2, 21, 22).

The number of genes encoding transcription factors (TFs) differentially expressed considerably increased in uninfected plants compared to infected plants treated with sylA (Table 8.3, rows #1243ff). As evident from figure 4.12, transcripts of genes encoding members of the NAM (No Apical Meristem), WRKY, and heat shock transcription factor (Hsf) families strongly accumulated upon sylA treatment.

Figure 4.12 SylA-dependent alteration of transcript abundance of genes encoding transcription factors

Syringolin application on Arabidopsis alters the expression of genes encoding members of different transcription factor families (X-axis). The Y-axis represents the number of genes whose expression was enhanced (filled column elements) or lowered more than 3-fold (open column elements) in each category. Abbreviations: bHLH, basic helix loop helix; bZIP, basic leucine zipper; HSF, heat shock factor; NAM, no apical meristem; DREB, drought responsive element binding factor.

Table 4.10 gives an overview of transcription factor families encompassing predominantly members that were transcriptionally induced by syringolin. These included members of the DREB (Drought Responsive Element Binding) TF family that specifically bind to promoter elements of stress responsive genes. Transcript levels of genes encoding members of the subfamily A-2 of DREB TFs were enhanced by sylA and the expression of one of them (Table 4.10, At2g38340, row #1) was strongly upregulated in infected and uninfected plants as reflected by corresponding t/c ratios (67,0 (IS12) and 530,6 (S12), respectively). In contrast, the majority of genes encoding members of the subfamilies A-4, A-5, and A-6 was downregulated by sylA in uninfected plants (Table 4.10, rows #6ff).

The NAM proteins have been implicated in a variety of processes in plant development, including the maintenance of the shoot apical meristem and the formation of lateral roots (Xie et al., 2000). Members of the NAM protein family were transcriptionally upregulated by syringolin, and the gene encoding ANAC094 (Table 4.10, At5g39820, row #26) exhibited high induction values in infected and uninfected plants.

In addition, syringolin predominantly induced the expression of genes belonging to the heat shock transcription factor (Hsf) class A whose members are primarily responsible for stress-inducible activation of heat shock genes (Czarnecka-Verner et al., 2000). The gene encoding HSFA2 (Table 4.10, At2g26150, row #31) was upregulated in infected tissue 2-4 hat (IS4) and exhibited higher expression in experiment S12, where uninfected plant material was collected at the late timepoint of 8-12 hat. Among further Hsfs, the expression of only one gene, encoding HSFC1 (Table 4.10, At3g24520, row #37), was repressed by sylA. Interestingly, HSFC1 proteins compose a new class of Hsfs that is clearly separated from all others Hsfs by sequence details and by the characteristics of the HR-A/B region (Nover et al., 2001).

Finally, WRKY proteins have been shown to be strongly involved in the alteration of gene expression in response to microbial pathogens and pathogen elicitors (Asai et al., 2002; Chen and Chen, 2002; Eulgem et al., 1999). Interestingly, WRKY6, transcriptionally induced by syIA (Table 4.10, At1g62300, row #38), was found to play a role during plant senescence (Robatzek and Somssich, 2002) and was upregulated upon treatment with bacterial flagellin (Navarro et al., 2004).

- (2) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$). Dashes designate genes that have not passed the Welch's t-test.
- (3) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$) and MTC. Dashes designate genes that have not passed the Welch's t-test and MTC.

A further group of genes involved in transcriptional processes was represented by the histone family genes, whose expression was downregulated more than 3-fold by sylA in uninfected plants (Table 8.3, rows #1412ff). Histones have structural roles in the formation of protein cores around which DNA is folded. Chromosome duplication during S phase of the eukaryotic cell cycle requires both replication of genomic DNA and the synthesis of histones, which are assembled with the newly synthesised DNA into chromatin fibers. In addition, syringolin application on uninfected plants enhanced the expression of the *Cdc48* gene (Table 8.3, At3g09840, row #1222) and its homologs. This indicates that syringolin directly or indirectly influences cell cycle progression or cell division.

Several transcripts encoding proteins involved in transport processes were downregulated by syIA application on uninfected plants. This concerned cellular transport of amino acids, lipids, peptides and sugars (Figure 4.13).

Figure 4.13 Influence of syringolin on cellular transport processes

Syringolin application on *Arabidopsis* alters the expression of genes encoding proteins involved in different cellular transport processes (X-axis). The Y-axis represents the number of genes whose expression was enhanced (filled column elements) or lowered more than 3-fold (open column elements) in each category.

Genes encoding ABC (ATP-Binding Cassette)-transporters and MATE (Multidrug And Toxic compound Extrusion) efflux proteins, involved in cellular detoxification, were induced by syringolin. A similar number of genes belonging to these protein families was downregulated by syringolin in uninfected plants.

Cyclic nucleotide-gated channels (CNGCs) are activated by cyclic nucleotides and exhibit permeability to monovalent and divalent cations. Genes encoding CNGCs were present among genes upregulated as well as downregulated by syIA.

A high number of genes encoding major intrinsic proteins (MIPs), membrane channels involved in water transport, uncharged solutes, gases and micro-nutrients (Tyerman et al., 2002) was downregulated by syIA. An inhibition of genes encoding

MIPs has been shown in plants during water deficiency (Aharon et al., 2003) and has been reported as a consequence of a drop in cytosolic pH associated with low-oxygen stress (Liu et al., 2005).

In addition, syringolin enhanced transcript abundance of proteins directing transport between different cellular compartments, such as nuclear importin alpha-1 and alpha-2 (Table 8.3, At3g06720, At4g02150, rows #1683, 1684) which mediate nuclear transport, as well as TIM17-1 and TOM20-4 (Table 8.3, At1g20350, At5g40930, rows #1660, 1661), mitochondrial translocases in the inner and outer membrane.

Abundance of transcripts corresponding to genes involved in cellular vesicle trafficking was elevated (Table 8.3, rows #1764ff). This included membrane associated family proteins known as SNAREs which play a role in membrane fusion and are central to the process of secretory vesicle targeting (Bock et al., 2001). The formation of a tight complex between two target SNAREs, syntaxin and a SNAP25-like protein, and one or more vesicular SNAREs is necessary to drive membrane fusion.

Remarkable changes in transcript abundance were also found for auxin-responsive genes. The majority of these genes had lowered expression values after sylA treatment (Table 8.3, rows #904ff). Similarly, the expression of genes encoding proteins involved in gibberellin, cytokinin, brassinosteroid and jasmonate signalling was repressed by sylA (Figure 4.14). For example, genes encoding lipoxygenase 2 and 3 (Table 8.3, At3g45140, At1g17420, rows #985, 986) involved in jasmonate biosynthesis were less expressed, whereas transcript abundance of the lipoxygenase 1 gene (Table 8.3, At1g55020, row #981) was enhanced by sylA. A considerable number of genes involved in ethylene and abscisic acid-signalling was also induced by sylA (Figure 4.14).

Figure 4.14 SylA-dependent alteration of transcript abundance of genes encoding proteins involved in plant hormone physiology

Syringolin application on *Arabidopsis* alters the expression of genes encoding proteins related to hormone signalling. The X-axis represents different groups of plant hormones. The Y-axis represents the number of genes whose expression was enhanced (filled column elements) or lowered more than 3-fold (open column elements) in each category.

Syringolin application on uninfected plants enhanced transcript abundance of genes encoding proteins responding to biotic stimuli. This included PAD3 and PAD4 (Table 8.3, rows #1116, 1142), both involved in phytoalexin biosynthesis, together with CPR5, EDS5 and RAR1/PBS1 (Table 8.3, rows #1115, 1131, 1145), which are components of distinct R-gene mediated pathways. Some of them are also required for the expression of basal defences against several virulent pathogen strains. The product of *Yls9/Nhl10* (Table 8.3, At2g35980, row #1138), a homolog of the tobacco *Hin1* gene, belongs to the harpin-induced protein family and was activated 71-fold upon *sylA* treatment. Interestingly, transcripts of the *Hin1* gene specifically accumulated when host plants were inoculated with avirulent bacterial strains but not after infection with virulent strains (Varet et al., 2003; Zheng et al., 2004), indicating HR-related expression.

However, syringolin was also found to exert repressive effects on disease resistance genes as reflected by downregulation of several of these genes (Table 8.3, rows #1151ff), genes involved in the synthesis of flavonoid and isoflavonoid secondary metabolites (Table 8.3, rows #336ff), and several pathogenesis-related (PR) proteins (Table 8.3, rows #1162ff).

Prominent groups of genes that were not classified to a distinct category according to biological function GO terms are presented in figure 4.15. As shown there, transcripts corresponding to all representatives of the oxidase, glucosidase and GDSL-lipase families and the majority of the glucanases and UDP-glycosyltransferases were lowered in abundance. Transcripts encoding members of the glutathione-S-transferase family increased and decreased by approximately equal numbers after syringolin treatment.

Figure 4.15 Influence of syringolin on enzyme activity

Syringolin application on Arabidopsis alters the expression of genes encoding members of different enzyme families (X-axis). The Y-axis represents the number of genes whose expression was enhanced (filled column elements) or lowered more than 3-fold (open column elements) in each category.

With the aim to gain insight in expression changes in plants very early upon syringolin treatment we analysed alteration in transcript abundance one hour after syringolin application (S1). This revealed that the abundance of the majority of transcripts was reduced by sylA. This repressive effect of sylA was similarly observed at the later timepoints (S12) where the expression of more genes was downregulated by sylA.

As is obvious from table 4.11 which represents all genes more than 2-fold differentially expressed in experiment S1, the gene exhibiting highest induction values encoded the PR-1 (pathogenesis-related) protein (Table 4.11, At2g14610, row #38). Remarkably, the expression of genes encoding pathogenesis-related proteins was repressed by sylA at later timepoints (Table 8.3, rows #1162ff).

In summary, syringolin application on uninfected tissue lead to a change in transcript levels suggesting an inhibition of various metabolic processes, including primary metabolic pathways such as photosynthetic activities. In contrast, cellular processes related to the mitochondrion appear to be induced by syringolin, as reflected by often strong transcriptional induction of several mitochondrial proteins. In fact, activities related to detoxification and drought stress tolerance appeared also to be induced indicated by enhanced transcript abundance of corresponding genes. The expression of genes related to signal transduction was enhanced as represented by elevated transcript abundance of genes encoding members of the WRKY TF family and proteins involved in calcium signalling. In contrast, syringolin was found to have inhibitory effects on the expression of a high number of defence-related genes and genes encoding receptor-like kinases.

RESULTS

(1) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>).

(2) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$) and MTC. Dashes designate genes that have not passed the Welch's t-test and MTC.

4.2 Functional characterisation of syringolin-responsive genes

Gene disruption by T-DNA insertion is a powerful tool for obtaining knock-out mutants that help in ascertaining biological function of uncharacterised open reading frames.

With the aim to identify genes responsible for sylA-mediated resistance against powdery mildew, we investigated knock-out mutants harbouring T-DNA insertions in genes activated by syringolin. Candidate genes were chosen among transcripts that accumulated early upon sylA treatment and were present in experiment IS4, and genes that exhibited strong induction values in experiment S12 (Table 4.12).

Table 4.12 T-DNA insertion lines for selected genes

Row	Description	T-DNA line	Insertion	Locus ¹	t/c ratio	
					IS4 ²	S12 ³

- (1) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>).
- (2) T/c ratios of genes that have passed Welch's t-test ($p \leq 0.05$). Dashes designate genes that have not passed Welch's t-test ($p \leq 0.05$).
- (3) T/c ratios of genes that have passed Welch's t-test ($p \leq 0.05$) and MTC.
- (4) No homozygous plants obtained.

Emphasis was given to proteins that have a function in regulative processes such as transcription factors (Table 4.12, rows #7, 8, 9, 12, 13) and proteins related to cellular signal transduction (Table 4.12, row #6). No homozygous T-DNA insertions were detected for *salk_023227* and *salk_143574*, suggesting that homozygous insertions are lethal.

The isolation and verification of homozygous insertion mutants was performed by PCR. Gene-specific PCR primers flanking the insertion were used in combination with a primer corresponding to the T-DNA left border (primer sequences are given in section Materials and Methods, chapter 6.9.1). PCR amplification using wild type DNA should yield a fragment only with the gene-specific forward (Gf) and reverse (Gr) primers, whilst amplification of a smaller fragment using the respective gene specific primer and the T-DNA left border primer (LBa1 or LBb1) indicates a T-DNA insertion. Following PCR amplification, DNA extracted from plants heterozygous for the insertion should yield a product with either set of primers, whereas DNA from plants homozygous for the insertion would only yield a product with the LBa1/LBb1 and one of the Gf/r primers. A representative example showing the identification of heterozygous and homozygous insertion lines is shown in figure 4.16.

Figure 4.16 Identification of knock-out mutants homozygous for the T-DNA insertion

T-DNA insertion lines were analysed for homozygous insertions by using gene-specific primers (Gr/f). 1: PCR with wild-type DNA (wt - no insertion) should result in a product of 881 bps (from Gf to Gr). 2: DNA from homozygous plants (hm - insertions in both chromosomes) will result in a band of 358 bps (e.g. salk_000794). 3: Heterozygous plants (hz) exhibit both bands. PCR aliquots were analysed on 1,5% agarose gels. M: marker.

Mutant lines successfully reconfirmed for homozygous T-DNA insertions were propagated and analysed for *sylA*-insensitivity. The assay was based on the microscopic evaluation described in chapter 4.1.2.1. Accordingly, 14-day-old seedlings were infected with powdery mildew and sprayed with a 20 μ M syringolin solution 48 hours after infection. To decrease the occurrence of sporadic sporulation which directly correlates with inoculation density, leaves were lightly infected by brushing down spores from highly infected *Arabidopsis* plants (see section Materials and Methods, chapter 6.3.2). Leaf material was collected for microscopic evaluation 72 hat, at which point first conidiophores started to develop on control-treated leaves (Figure 4.3 C), but no sporulation occurred on *sylA*-treated wild-type leaves (Figure 4.4 A). Evaluation of plant material at the timepoint when first conidiophores just started to develop increased the stringency of the assay.

Sporulation efficiencies were evaluated according to the scheme shown below in table 4.13:

Table 4.13 Scheme for evaluation of sporulation efficiency

Description	Phenotype
	Number of conidiophores/leaf
weak sporulation	0 - 3
intermediate sporulation	3 - 15
heavy sporulation ¹	> 15

- (1) If heavy sporulation was confined to a distinct leaf area, the phenotype was evaluated as 'intermediate sporulation'.

On average, 28 leaves were analysed by bright field microscopy for each insertion line, together with an equal number of wild-type plants. In addition, four to six plants were infected and sprayed with a control solution to visualise proper fungal growth. Sporulation efficiencies were investigated for all T-DNA insertion lines and the results in terms of numbers are given in table 4.14.

Table 4.14 Effect of T-DNA insertion in respective *sylA*-inducible genes on the response of powdery mildew-infected plants towards syringolin

Experiment ¹	T-DNA line	Sporulation efficiency [%] ²		
		weak sporulation	intermediate sporulation	heavy sporulation
1	wild type	94	6	0
	salk_120950	100	0	0
	salk_018840	100	0	0
2	wild type	98	2	0
	salk_021881	94	4	2
3	wild type	98	2	0
	salk_051751	95	5	0
4	wild type	52	31	17
	gabi_027D08	63	27	10
	salk_144950	64	22	14
5	wild type	54	38	8
	salk_000794	100	0	0
	salk_123169	51	44	5
	salk_057603	95	5	0
	salk_005507	70	24	6
6	wild type	55	31	14
	salk_041367	57	36	7

- (1) For each experiment an equal number of wild-type plants was analysed together with the T-DNA insertion lines.
- (2) Sporulation efficiency was evaluated according to the scheme presented in table 4.13.

As obvious from table 4.14, all mutant lines exhibited similar responsiveness towards sylA treatment as wild-type plants. Thus, loss-of-function mutation of the 11 genes tested did not result in increased insensitivity towards syringolin. However, unexpectedly, one mutant line revealed an effect independent of syringolin. The respective mutant line (salk_000794), isolated for a T-DNA insertion in the At4g12400 gene (stress-induced protein/ sti1-like protein), showed impaired growth of the powdery mildew fungus on control and non-treated leaves. Macroscopically, we observed yellowed borders of infected salk_000794 leaves (Figure 4.17 A), which became never visible on infected wild-type leaves (Figure 4.17 B). By five days after inoculation, *E. cichoracearum* developed extensive hyphal growth that nearly covered the leaf surface on both salk_000794 and wild-type plants. By day seven, the number of conidiophores was severely reduced on salk_000794 leaves (Figure 4.17 C) whereas, *E. cichoracearum* developed abundant conidiophores on wild-type Columbia plants (Figure 4.17 D). Visible chlorosis in salk_000794 plants just began before the formation of numerous conidiophores macroscopically visible as white powder on wild-type plants six days after infection. The salk_000794 T-DNA insertion line developed only small scattered patches of powder. On uninfected salk_000794 plants, the occurrence of spontaneous lesions such as necrosis or chlorosis was not detectable. Growth and reproduction rate was comparable to wild-type plants (data not shown).

Figure 4.17 Development of powdery mildew on salk_000794 T-DNA insertion line

Salk_000794 mutant plants were infected with powdery mildew. Seven days after infection, symptoms such as chlorosis, starting at the leaf borders, became clearly visible (A) but were not detectable on infected wild-type leaves (B). For bright field microscopy leaves were destained by overnight incubation in lacto-phenol solution and fungal structures were stained with coomassie blue. Microscopic evaluations revealed that sporulation was impaired on salk_000794 mutant plants (C), whereas powdery mildew colonisation was successful on wild-type plants (D). Scale bars in A and B: 2 mm, scale bars in C and D: 100 μ m.

Investigation of conidiophores that developed on salk_000794 revealed that sporogenesis was not only reduced but also distorted. The reduced ability to stain conidiophores with coomassie blue as compared to conidiophores from wild-type plants (Figure 4.18 A) indicated degradation of proteins and a starting collapse of conidiophores (Figure 4.18 B and C).

Figure 4.18 Degradation stages of conidiophores on leaves of salk_000794

Leaves of salk_000794 T-DNA insertion line were destained in lacto-phenol solution and were stained for fungal structures with coomassie blue seven days after infection. Intact conidiophores (A). Different stages of protein degradation in conidiophores on leaves of salk_000794 (B and C). Scale bar: 50 μ m.

As expected for a line homozygous for a T-DNA insertion the phenotype was maintained in the offspring. The F1 progeny of a cross between the salk_000794 line and the wild type exhibited sporulation efficiencies similar to wild-type plants, indicating that the mutation was recessive.

Plants homozygous for the T-DNA insertion in the genomic sequence of At4g12400 were identified by PCR with T-DNA left border primer LBb1 and the respective gene-specific primers Gf or Gr. The PCR products were then purified and sequenced to precisely determine the location of the T-DNA insertion (Figure 4.19).

Figure 4.19 Diagram of At4g12400 gene sequence and the positions of T-DNA insertions

Coding regions (exons) are represented by white boxes, non-coding regions are shaded in dark grey (introns) and UTRs at 5' and 3' ends in light grey. Horizontal arrows indicate directions of transcription. Numbers specify positions in the sequence in terms of base pairs. The position of insertion is indicated above the gene diagram, depending on the direction of inserted T-DNA. The scheme is drawn to scale. LBb1: left border primer 1, Gf and Gr: gene specific forward and reverse primers.

As shown in figure 4.19, for insertion line salk_000794 the T-DNA was located within the first exon.

Consistent with gene chip data, semi-quantitative determination of mRNA expression in wild-type plants revealed that the gene (At4g12400) was induced weakly by control treatment but strongly by sylA treatment. As expected, no expression was found in sylA-treated salk_000794 T-DNA insertion lines (Figure 4.20).

Figure 4.20 mRNA levels of At4g12400

At4g12400 transcript levels were determined by RT-PCR in wild-type (wt) plants and insertion line *salk_000794*. Plants were treated either with a control solution (c) or a 20 μ M solution of sylA (sylA). The PCR product has an expected size of 376 bp. PCR aliquots were analysed on 1,5% agarose gels.

A second independent knock-out line (*flag_013C07*) with a T-DNA insertion in the genomic sequence of the *At4g12400* gene was included in our studies. Preliminary results of plants homozygous for the T-DNA insertion in the *At4g12400* genomic sequence revealed a phenotype similar to *salk_000794*, i.e. impaired sporulation of powdery mildew. This confirmed that loss-of-function of the *At4g12400* gene negatively affects powdery mildew reproduction in *Arabidopsis*.

At present the function of the *At4g12400* encoded protein in *Arabidopsis* is unknown. Homologous genes have been identified in soybean and rice. These genes carry tetratricopeptide repeats which so far are rarely present in plant derived gene sequences. The soybean gene encodes a protein with high identity to the yeast stress-inducible protein and its expression is inducible by heat (H ernandez Torres et al., 1995). Therefore, it seems likely that the *At4g12400* encoded protein may similarly exhibit a stress-related function in *Arabidopsis*.

4.3 Screening for mutants insensitive to syringolin

In a second approach for the identification of genes responsible for *sylA*-mediated resistance against powdery mildew a M2 population of 14-day-old EMS-mutagenised *Arabidopsis* seeds (ecotype Columbia) was screened for less or no impairment of fungal growth after syringolin application. The EMS-mutagenised seeds were purchased from Lehle Seeds (Round Rock, TX, USA). Sporulation efficiency after *sylA* treatment was tested for 25'250 EMS-plants corresponding to approximately 3000 M2 families. Potential mutants were self-pollinated and offspring (M3) were assayed in a second round of screening. The screening was carried out in cooperation with Dr. Roshani Shakya (a former post-doc in the group of Prof. Robert Dudler) and revealed one confirmed mutant. This mutant was referred to as *syl_404*.

In general, *syl_404* plants were more sensitive to syringolin treatment as expressed by slight osmotic stress symptoms macroscopically visible by slight leaf-wilting shortly after treatment with syringolin. Nevertheless, plants were found to recover within minutes after the liquid had evaporated on the leaf surface. On uninfected plants, wilting upon syringolin treatment was observed rarely. The wilting was stronger on plants which were infected prior to syringolin treatment. Recovery was dependent on infection density and on the amount of syringolin applied on the leaf surface. In rare cases, infected and *sylA*-treated plants were not able to recover and died.

To verify the mutant phenotype conferred by *syl_404*, 14-day-old seedlings in the M3 generation were infected with powdery mildew as described in chapter 6.3.2. Plants were sprayed with a 20 μ M syringolin solution 48 hours after infection and leaf material was collected for microscopic evaluation five days post-inoculation.

Insensitivity of syl_404 plants to syringolin was expressed by the formation of a higher number of conidiophores upon syringolin treatment compared to the number of conidiophores developed on syringolin-treated wild-type plants. Three classes, reflecting the sporulation efficiency upon syringolin treatment, were formed based on the number of conidiophores developed on the plants according to the scheme presented in table 4.13. Figure 4.21 shows typical examples of the three classes: weak sporulation (Figure 4.21 A), intermediate (Figure 4.21 B) and heavy sporulation (Figure 4.21 C). Enlargements illustrate that on leaves exhibiting weak sporulation, the fungus was stopped in further growth (Figure 4.21 a) whereas on leaves classified as heavy sporulation the fungus was able to form conidiophores (Figure 4.21 d). Both phenomena, heavy and weak sporulation, may occur on leaves classified as intermediate (Figure 4.21 b and c).

Figure 4.21 Characterisation of plant-pathogen interactions on mutant syl_404

Leaves of mutant syl_404 were infected with powdery mildew and treated with sylA 48 hours after infection. Seventy-two hours after treatment, plant material was destained by over-night incubation in lacto-phenol solution and fungal structures were stained with coomassie blue. Sporulation efficiency was determined according to the scheme presented in table 4.13. Examples of 'weak sporulation' (A), 'intermediate sporulation' (B) and 'heavy sporulation' (C) are illustrated. Representative parts in A-C are enlarged in a-d. Scale bar: 100 μ m.

The results derived from two independent experiments are presented in figure 4.22 and corresponding values are given in table 8.4 (Appendix E). For each experiment, on average, 47 leaves of mutant syl_404 and the wild type were analysed microscopically. In addition, four to six wild-type plants were infected and sprayed with a control solution to visualise proper fungal growth.

As shown in figure 4.22, sporulation efficiency after sylA application was drastically enhanced on syl_404 as compared to wild-type plants.

Figure 4.22 Sporulation efficiency on mutant_404 after sylA treatment

Leaves of syl_404 and wild-type plants were infected and treated with sylA 48 hai. Interactions were scored 72 hat. Sporulation efficiency was determined according to the scheme presented in table 4.13 and related to the total number of plants evaluated (100%).

With the aim to eliminate other, additional mutations caused by EMS-mutagenesis, syl_404 was backcrossed to a Columbia wild-type plant and F1 seeds were allowed to self-pollinate to produce F2 seeds. Following this, F2 plants were tested for syringolin-insensitivity. Investigation of 18 F2 plants revealed two plants

exhibiting fungal sporulation after sylA treatment. The segregation ratio of approximately 3:1 in those F2 plants that do not or do support fungal growth with sylA application indicated a recessive mutation (Table 4.15). This suggestion is supported by the finding that infected and sylA-treated F1 plants, which are heterozygous for the mutation, exhibited a wild-type phenotype and did not show increased sporulation efficiency (data not shown).

Table 4.15. Powdery mildew sporulation efficiency on backcross lines

Plants	Sporulation efficiency [number of plants] ¹		
	weak sporulation	intermediate sporulation	heavy sporulation
wild type	12	1	0
syl_404 F2 population	14	2	2 ²

- (1) Sporulation efficiency was evaluated according to the scheme presented in table 4.13.
- (2) Plants chosen from F2 population exhibiting heavy sporulation after sylA treatment.

The F2 individuals exhibiting sporulation were referred to as syl_404_bc1 (bc=backcross) and syl_404_bc2. These putative sylA-insensitive mutant lines were infected and treated with sylA as described. The results obtained for syl_404_bc1 and syl_404_bc2 in six independent experiments are illustrated in figure 4.23 and corresponding values are given in table 8.5 (Appendix E). For each experiment an equal number of plants from original syl_404 (M3 plants) and wild-type plants was analysed together with the backcross lines.

Figure 4.23 Sporulation efficiency on backcross mutant lines

Plants derived from the F2 population of syl_404_bc1 and syl_404_bc2, the original parental line and wild-type plants were infected and treated with sylA 48 hai. Interactions were scored 72 hat. Sporulation efficiency was evaluated according to the scheme presented in table 4.13 and related to the total number of plants evaluated (100%).

Figure 4.23 shows that fungal sporulation efficiency was enhanced on backcross lines syl_404_bc1 and syl_404_bc2 as compared to infected and sylA-treated wild-type plants. Reduced sporulation efficiency was comparable to the results obtained for powdery mildew-infected and sylA-treated original syl_404.

In summary, these results indicate that syl_404 harbours a mutation in a gene that might be involved in the curative effect of syringolin on powdery mildew-infected *Arabidopsis thaliana* plants.

4.3.1 Transcriptional analysis

With the aim to identify transcriptional differences in the syringolin response between syl_404 and wild-type plants, we compared transcript accumulation between sylA-treated backcross line syl_404_bc2 (in the following referred to as syl_404 for simplicity) and sylA-treated wild-type plants using the ATH1 Affymetrix gene chip. To reduce the impact of pool sampling on data variation, plant material was collected from a single timepoint experiment eight hours after treatment. In the following this experiment is referred to as experiment S8.

The experiments were repeated in duplicates. In case of few replicates available, Genespring recommends to statistically filter on relevant genes by assuming that variances are equal between two groups (see section Materials and Methods, chapter 6.8.2). Consequently, reliable data were filtered using Student's t-test (variances equal) including a multiple testing correction according to Benjamini and Hochberg (Benjamini and Hochberg, 1995).

RNA extraction was performed according to previous experiments. Synthesis of labelled cRNA was performed according to the Affymetrix one-sample protocol. For the one-sample protocol *in vitro* transcription was extended from 4,5 hours to overnight incubation.

The results in terms of numbers of transcripts whose levels were enhanced and lowered more than 2-fold and more than 3-fold in experiment S8 are presented in table 4.16.

Table 4.16 Numbers of differentially expressed transcripts

	t/c ratio ¹			
	≥ 2	≤ 0,5	≥ 3	≤ 0,333
wild type	1629	1973	973	1231
syl_404	1959	2093	1096	1459

- (1) Data derived from two independent experiments. Differentially expressed genes were filtered by Student's t-test ($p \leq 0.05$) and MTC.

Reproducibility of transcriptional changes caused by syringolin application in experiment S8 was investigated by comparing transcript accumulation in sylA-treated wild-type plants to a previously performed experiment (S12) where RNA derived from uninfected sylA-treated wild-type plant material collected 8 and 12 hat. This revealed that out of the 1629 genes whose expression was enhanced more than 2-fold in experiment S8, the expression of 1206 transcripts was similarly enhanced more than 2-fold in experiment S12. As shown for experiment S8 in table 4.16, the majority of more than 2-fold differentially expressed genes was downregulated by syringolin in syl_404 and wild-type plants. Concerning the 1973 genes downregulated more than 2-fold in the wild type by syringolin (S8), the abundance of 1622 transcripts was also lowered more than 2-fold in the wild type by syringolin in experiment S12. Accordingly, transcriptional changes exerted by syringolin appear to be comparable. However, it seems likely that different timepoints of sample collection as well as modification of target labelling and gene chip hybridisation (see section Materials and Methods, chapter 6.8.1) might have provoked a certain transcriptional variability. The distributions of values of differentially expressed genes 8 hat in wild-type and syl_404 plants are given in a Venn diagram in figure 4.24.

Figure 4.24 Comparison of *sylA*-responsive gene expression in *syl_404* and wild-type plants

The Venn Diagram represents the distribution of more than 2-fold significantly (p -value ≤ 0.05 , MTC) expressed genes in *syl_404* and wild-type (WT) plants. (A): overlap between differentially expressed genes in *syl_404* and upregulated genes in wild-type plants. (B): overlap between differentially expressed genes in *syl_404* and downregulated genes in wild-type plants.

We focused on genes differentially expressed between wild-type plants and *syl_404*, such as genes more than 2-fold upregulated in wild-type plants but downregulated in *syl_404*, which was the case for five genes (Figure 4.24 A). These genes and corresponding t/c ratios are given in table 4.17.

Table 4.17 Genes more than 2-fold differentially expressed between wild-type and *syl_404* plants

Row	Description	Protein	Locus ¹	t/c ratio ²	
				wt	<i>syl_404</i>
1	MATE efflux family protein		At3g23550	12,4	0,3
2	fibrillarin 2 identical to fibrillarin 2	Fib2	At4g25630	2,3	0,5
3	curculin-like (mannose-binding) lectin family protein		At5g18470	4,9	0,3
4	auxin conjugate hydrolase	ILL5	At1g51780	2,1	0,4
5	WRKY family transcription factor	WRKY53	At4g23810	5,8	0,4

- (1) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>).
- (2) Data derived from two independent experiments. Differentially expressed genes were filtered by the Student's t-test ($p \leq 0.05$) and MTC. wt: wild type.

The reverse case, i.e. genes downregulated in the wild type and upregulated in syl_404, was not found (Figure 4.24 B). Among genes with an absent call for the detection value in all experiments performed with RNA derived from syl_404 plants, seven genes were found that received a present call in wild-type plants. However, these genes were neither upregulated nor transiently expressed but downregulated at least 1,6-fold by syringolin in the wild type (data not shown).

Inspection of raw values obtained from control (0,05% TWEEN 20)-treated wild-type and syl_404 plants made it obvious that the abundance of many transcripts was already altered in the mutant without sylA treatment. Consequently, this resulted in decreased t/c ratios of these genes. To compare absolute transcript abundances between wild-type and syl_404 plants, ratios were calculated derived from sylA-treated wild-type and syl_404 plants. Similarly, mutant/wild-type ratios (m/wt ratios) were calculated from the data derived from control-treated wild-type and syl_404 plants.

In total, m/wt ratios ≥ 3 and $\leq 0,333$ were found for 514 genes in control-treated syl_404 plants and for 333 genes in syringolin-treated syl_404 plants, respectively. However, average signal values over all genes obtained from control- and syringolin-treated syl_404 plants were similar.

Genes whose m/wt ratios were altered more than 3-fold by control and/or syringolin treatment in syl_404 were grouped according to biological function GO (Gene Ontology) terms and are listed in table 8.6 (Appendix F). The distribution of transcripts in functional categories for control (c) or syringolin (s) treatment is illustrated in figure 4.25.

For several functional categories transcript abundance in syl_404 was higher than in the wild type without sylA treatment (Figure 4.25). Remarkably, strongest alteration in transcript abundance upon control treatment in syl_404 compared to wild-type plants was found for genes encoding proteins responding to abiotic and biotic stimuli.

Figure 4.25 Impact of control and syringolin treatment on gene expression in *syl_404* plants

Genes differentially expressed between wild-type and *syl_404* plants upon treatment with a control solution (c) or syringolin (s). Transcripts were categorised according to biological function GO terms as represented on the X-axis. The Y-axis represents the number of genes whose expression was enhanced (filled column elements) and lowered more than 3-fold (open column elements) in each category.

Table 4.18 represents an overview of transcripts whose abundances were altered more than 10-fold by control and/or syringolin treatment in *syl_404* as compared to the wild type.

Table 4.18 Functional groups of genes exhibiting m/wt ratios ≥ 10 and $\leq 0,1$ in syl_404 upon control and/or syringolin treatment

- (1) Transcripts were grouped according to biological function GO (Gene Ontology) terms. Genes with unknown biological functions were excluded from table 4.18.
- (2) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>).
- (3) Data derived from two independent experiments: m/wt ratios were calculated from the data derived from control-treated syl_404 (m) and wild-type (wt) plants. Genes that passed statistical filtering based on Student's t-test ($p \leq 0.05$) are highlighted in bold.
- (4) Data derived from two independent experiments: m/wt ratios were calculated from the data derived from syringolin-treated syl_404 (m) and wild-type (wt) plants. Genes that passed statistical filtering based on Student's t-test ($p \leq 0.05$) are highlighted in bold.
- (5) Data derived from two independent experiments: t/c ratios were calculated from the data derived from wild-type (wt) and syl_404 plants. Genes that passed statistical filtering based on Student's t-test ($p \leq 0.05$) and MTC are highlighted in bold.

Transcripts exhibiting strong syringolin-independent expression in syl_404 included genes encoding proteins related to abscisic acid (ABA) signalling and drought stress (Table 4.18, rows #1ff). Among them, the gene encoding an ABA-responsive protein revealed a dramatic expression ratio in control-treated and syringolin-treated syl_404 plants (Table 4.18, At3g02480, row #1). In some cases, low m/wt ratios in syringolin-treated syl_404 plants resulted from elevated expression levels of the respective genes in the wild type upon syringolin treatment as reflected by corresponding t/c ratios.

Genes with high transcript levels in control-treated syl_404 plants were also related to the jasmonic acid signalling pathway (Table 4.18, rows #10ff), which is generally involved in a number of biotic and abiotic stress responses. The abundances of the majority of these transcripts were lower in syringolin-treated syl_404 plants and downregulated by syringolin in the wild type. Interestingly, drought stress and endogenous ABA can upregulate a number of wound-inducible genes (Chao et al., 1999), and cellular responses to jasmonic acid can involve concomitant activation of ethylene response pathways (Creelman et al., 1992; Creelman and Mullet, 1995; Penninckx et al., 1998). Indeed, transcripts of genes encoding members of the ERF (Ethylene Responsive Factor) transcription factor family revealed high m/wt ratios in control-treated plants (Table 4.18, rows #46ff). Comparison to data available through the Genevestigator database (Zimmermann et al., 2004), which collects hundreds of microarray expression data sets, revealed that all except one (Table 4.18, At5g61890, row #48) of the ERF and WRKY transcription factors present in table 4.18 were transcriptionally inducible by ozone and infection with *Pseudomonas syringae*, indicating a role of these proteins in abiotic and biotic stress responses.

In addition, further genes involved in cellular stress responses, such as genes encoding proteins functioning during oxidative stress (Table 4.18, rows #22ff) revealed high transcript abundance in control-treated syl_404. Transcripts of these genes exhibited lower abundances in syringolin-treated syl_404. In addition, the majority of these genes was downregulated by syringolin in wild-type and syl_404 plants as reflected by corresponding t/c ratios. In contrast, genes encoding members of the cytosolic small Hsps revealed higher expression in syringolin-treated compared to control-treated syl_404 plants (Table 4.18, rows #30ff). Similarly, the gene encoding a glutamate decarboxylase (Table 4.18, At2g02010, row #43) exhibited higher expression in syringolin-treated syl_404 plants and its expression was dramatically upregulated by syringolin in the wild type.

In conclusion, it was found that only few genes exhibited antagonised expression in syl_404 compared to wild-type plants upon syringolin treatment. In general, transcriptional responsiveness of syl_404 differs from that in the wild type with regard to high expression of many stress-responsive genes without syringolin treatment. Transcripts of genes related to dehydration stress and ABA-signalling strongly accumulated in abundance in control-treated and syringolin-treated syl_404 plants and genes encoding small heat shock proteins exhibited high m/wt ratios in syringolin-treated syl_404 plants.

5 Discussion

5.1 Syringolin A action in *Arabidopsis thaliana*

In wheat, syringolin treatment effectively protects the plant from colonisation with virulent isolates of *Blumeria graminis* f. sp. *tritici*. This is also true for the interaction of powdery mildew (*Erysiphe cichoracearum*) with *Arabidopsis thaliana*. *Arabidopsis* offers several important advantages for the study of plant disease mechanisms in general and of powdery mildew disease in particular. Microscopic examination revealed that powdery mildew disease progressed similarly on *Arabidopsis* and on cereals, suggesting that information about the *Arabidopsis*-powdery mildew interaction will aid in understanding the more economically important powdery mildew disease of cereals. However, *Erysiphe cichoracearum* does differ morphologically from *Blumeria graminis* in germ tube development, conidiophore foot cell shape, and haustorium shape (Adam and Somerville, 1996).

Characterisation of the syringolin response in *Arabidopsis* revealed that syringolin efficiently protects the plant from colonisation by powdery mildew when applied two days after infection. By this time, the fungus has invaded the host cells and produced haustoria. By their feeding activities, biotrophic fungi create a nutrient sink at the infection site, so that the host is disadvantaged but not killed. Since powdery mildew depends on living host cells, plant cell death strategies are commonly most effective against this biotrophic fungus (Carver et al., 1999). Indeed, syringolin treatment of infected *Arabidopsis* causes autofluorescence, indicative for the occurrence of a hypersensitive reaction (Figure 4.4 B). In contrast to sylA-treated wheat, where autofluorescence was predominantly observed in epidermal cells, autofluorescence in *Arabidopsis* was weak in epidermal cells but strongly detectable

in underlying mesophyll cells at this timepoint (Figure 4.5). This is similar to the phenotypes conferred by *edr1* (*enhanced disease resistance 1*) plants with regard to inoculation with *E. cichoracearum* (Frye and Innes, 1998) and to phenotypes conferred by the late-acting resistance gene *Mla12* (*Mildew-resistance Locus A*) in barley (Hückelhoven and Kogel, 1998). In both cases, powdery mildew growth was affected after the development of secondary hyphae, but before conidiophore production. In addition, incompatible interactions in *Mla12* plants are associated with the accumulation of large masses of dead mesophyll cells (Boyd et al., 1995; Hyde and Colhoun, 1975). However, since powdery mildew does not infect mesophyll cells, and *sylA* does not lead to HR in uninfected tissue, *sylA*-triggered cell death in infected tissue must be in part due to effects the fungus exerts on neighbouring mesophyll cells. It is tempting to speculate that fungal infection triggers the diffusion of signal molecules such as ions or simple metabolites between infected and uninfected cells leading to HR in the surrounded tissue. Alternatively, membrane- or cell wall-bound macromolecules participating in the control of interactions between neighbouring cells may also be responsible for the signal transduction between infected and uninfected cells.

5.2 Transcript profiling of syringolin-treated powdery mildew-inoculated Arabidopsis

Microarray comparison between powdery mildew-infected and uninfected syringolin-treated Arabidopsis was carried out in order to identify genes transcriptionally involved in the localised induction of HR in *E. cichoracearum*-infected Arabidopsis plants.

Unexpectedly, no gene exhibiting a t/c ratio ≥ 2 in experiments IS1 and IS4 (plant material collected at 0.5-1 hat and 2-4 hat, respectively), has passed the statistical filtering when multiple testing correction was included (Table 4.2). However, we found a set of 47 genes differentially expressed more than 2-fold in uninfected plants treated with sylA (experiment S1). Thus, it appears that in uninfected plants more genes are reproducibly altered by sylA than in infected plants. This indicates that both parameters, infection and sylA treatment, applied together to the plant, might have provoked various cellular stresses leading to diffuse transcriptional changes at the early timepoint experiments (IS1 and IS4). In addition, large variation in gene expression very early after syringolin treatment together with low expression at these timepoints (data not shown) might have contributed to the reasons why no candidate gene passed stringent statistical filtering. However, one gene (At5g20630), encoding a germin-like protein 3 (GLP3), was more than 2-fold repressed in experiment IS1 when excluding the false positive correction (MTC) from the statistical filtering process. Because germins with oxalate-oxidase activity are involved in the elicitation of HR at lower concentrations of hydrogen peroxide and the destruction of oxalate, which is an inhibitor of the hypersensitive response (Lane, 2002), it was hypothesised that downregulation of *Glp3* by sylA might counteract the induction of HR. However, to date, the function of germin-like proteins from dicots remains uncharacterised with regard to their biochemical properties or antimicrobial activities (Lane, 2002).

Seventy-two genes were differentially expressed at least two-fold in experiment IS4 when MTC was excluded from statistical filtering (Table 4.2). All but two of the 68 genes ($p\text{-value} \leq 0.05$, no MTC) upregulated in infected tissue 2-4 hat were also included in the set of *sylA*-responsive genes upregulated in infected and uninfected plants by 8-12 hat. This finding indicates that the major changes exerted by *sylA* took place at later timepoints. This observation is supported by the high number of differentially expressed transcripts 8-12 hat in infected and uninfected tissue (Table 4.2). The remarkable changes in the transcriptome at the late timepoint (8-12 hat) of our hybridisation experiments is in accordance with earlier findings in syringolin-treated wheat leaves, where important transcriptional changes occurred 10 hours after syringolin application (Wäspi et al., 2001).

To our surprise, the effect of *sylA* on the transcriptome of *Arabidopsis thaliana* was dramatically higher in uninfected plants than in infected plants. It seems that the cellular response to syringolin was found to be negatively controlled by powdery mildew infection. Our microarray data suggest that in general this was not explicable by powdery mildew-induced accumulation of *sylA*-induced transcripts. Therefore, it was hypothesised that the observed reduced *sylA* response of powdery mildew-infected tissue may be due to a suppressive effect on gene expression the fungus exerts in colonised and neighbouring cells and was observed for a few specific genes in wheat (Wäspi et al., 2001).

However, 13 transcripts were identified that exclusively accumulated in infected tissue treated with *sylA* (Table 4.3). Apart from transcripts encoding proteins with unknown biological functions (Table 4.3, rows #2ff), two encoded a disease resistance protein containing a leucine-rich repeat domain and the WRKY75 transcription factor, respectively (Table 4.3, At2g34930, At5g13080, rows #1 and 13).

Interestingly, the WRKY75 transcription factor has a function during H₂O₂-mediated programmed cell death (Gechev et al., 2005) and was upregulated during programmed cell death (PCD) triggered in Arabidopsis by the fungal AAL-toxin (Gechev et al., 2004). Furthermore, this also included the *Pai3* gene (Table 4.3, At1g29410, row #10) encoding a protein involved in tryptophane biosynthesis. Since *Pai* isogenes were found to respond to environmental stresses, the expression of *Pai3* was possibly enhanced by excessive cellular stress imposed by a coincidence of both powdery mildew infection and syringolin treatment.

Thus, one hypothesis is that these transcripts might be linked to the occurrence of HR. Whether these genes might indeed encode proteins involved in the onset of HR in infected and sylA-treated tissue or whether the expression of these genes might rather be considered as a consequence of distinct cellular processes leading to HR remains to be determined.

Since one of the hypothesised functions of syringolin was to suppress a suppression of host responses imposed by the colonising fungus (Wäspi et al., 2001), we were interested in genes upregulated by powdery mildew infection but downregulated by syringolin. The single effect of infection on transcript abundance was calculated by comparing expression ratios derived from uninfected plants to infected plants, both treated with a control solution (I60). We identified 60 genes upregulated by powdery mildew infection alone but downregulated by syringolin application on uninfected plants (S12). Genes whose expression was induced by powdery mildew and repressed by sylA predominantly encoded proteins categorised to cellular transport, proteins that respond to biotic and abiotic stimuli as well as proteins involved in protein metabolism (Appendix C, Table 8.2).

Another interesting group is formed by three genes whose expression was repressed by the pathogen but enhanced by syringolin in infected tissue (Table 4.4). These genes encoded a disease resistance protein containing a leucine-rich repeat domain, an internal NAD(P)H dehydrogenase, and a MATE efflux (Multidrug And Toxic compound Extrusion) protein (Table 4.4, rows #1ff). Internal NAD(P)H dehydrogenases exhibit protective activity by providing a mechanism for plants to remove excess reducing power (Rasmusson et al., 2004). MATE efflux proteins play a role during cellular drug stress tolerance. In addition, six genes whose transcription levels were repressed by the fungus were more than 2-fold upregulated in uninfected plants by sylA (Table 4.4, rows #4ff).

In summary, several genes differentially expressed upon powdery mildew inoculation were found to exhibit opposite transcriptional regulation by syringolin. The encoded proteins might represent candidates that counteract fungal life to varying extent. However, it remains an open question how these proteins may contribute to antagonise powdery mildew growth on *Arabidopsis*. Moreover, transcriptional alteration by syringolin specific for infected tissue could only be shown for relatively few genes. Still, these genes encode proteins that might play a role during hypothesised HR in infected and sylA-treated cells. Nevertheless, these genes were induced only weakly.

5.3 Syringolin-induced genes in terms of biological functions

Plants infected with powdery mildew prior to sylA treatment apparently responded weaker to sylA. In contrast, in uninfected plants a large number of transcripts encoding proteins of a broad range of biological functions were affected. In the following, putative functions of these genes and their integration into different metabolic and regulative pathways are discussed.

5.3.1 Ubiquitin/26S proteasome pathway

In plants, the ubiquitin (Ub)/proteasome (26S) is involved in degrading a wide range of proteins. The importance of the Ub/26S system in plants is reflected by the identified high number of more than 1'300 genes (~5% of the total genome) in the *Arabidopsis* genome encoding Ub/26S components (Vierstra, 2003). A schematic overview of the Ub/26S pathway is shown in figure 5.1.

Figure 5.1 Schematic overview of the ubiquitin-proteasome pathway

E3 enzymes recognise substrates and mediate the transfer of ubiquitin from an E2. The latter receives its ubiquitin by transfer from an E1. Polyubiquitinated proteins are targeted for degradation by the 26S proteasome. Mono- and polyubiquitinated proteins can be deubiquitinated by the action of numerous deubiquitinating enzymes (DUBs). The 26S proteasome releases free ubiquitin and degrades the substrate to short peptides. The 26S multicatalytic proteinase complex is made up of the core 20S proteasome and PA700 activator (19S cap) (modified after Wojcik, 2002).

The 26S proteasome has a general function in the selective removal of various short-lived proteins that were first covalently linked to ubiquitin. Several of these proteins control key aspects of plant growth, development and defence (Callis and Vierstra, 2000; Hellmann and Estelle, 2002). The process of ubiquitination starts with the ubiquitin-activating enzyme (E1) which recruits ubiquitin and passes it to the ubiquitin-conjugating enzyme (E2), which transfers the ubiquitin to the ubiquitin ligase

protein (E3). The E3 is generally considered to be most important in controlling target specificity since it is responsible for recruiting the target protein (Vierstra, 2003).

The 26S proteasome complex consists of a 20S core protease (CP) capped by two particles of the PA700 proteasome activator, also called the 19S regulatory particle (RP). The 2.4 MDa proteolytic 26S proteasome complex of *Arabidopsis thaliana* has been isolated recently (Yang et al., 2004). The genomes of *Arabidopsis* and rice contain gene pairs for many CP and RP subunits (Fu et al., 1998). The 20S core particles carries two copies of the seven different α and β subunits arranged in four stacked rings. Representatives of all seven α and β subunits were found among genes upregulated by *sylA*, several were represented by pairs (Table 4.7).

The RP is subdivided into lid and base. Collectively, the RP assists in recognising appropriate substrates, unfolding them, opening the α -ring gate, and then directing the unfolded polypeptides into the lumen of the CP for breakdown. Genes encoding pairs or single representatives of all of these subunits exhibited elevated expression upon *sylA* treatment. Four genes encoding RP and CP subunits exhibited enhanced expression already 2-4 hat (Table 4.7).

At present, only the functions of a few of the core RP subunits are known. For the majority of subunits both pairs were induced by syringolin. An exception was found for RPN12a (Table 4.7, At1g64520, row #34), indicating that paralogs might exhibit different activities. Indeed, RPN12a and RPN12b display enough structural divergence to support this assumption (Yang et al., 2004). Another exception was subunit RPN3a (Table 4.7, At1g20200, row #24), which is distinguished from its paralog by the absence of a nuclear localisation signal (Yang et al., 2004).

An increase of the 26S proteasome level might reflect a higher demand for protein degradation via the ubiquitin pathway after *sylA* treatment. In fact, the presence of a distinct set of proteasome subunits together with the finding that some transcripts which accumulated already 2-4 h after treatment encoded RP and CP subunits might hint at the formation of specialised proteasome complexes upon *sylA* treatment (Table 4.7).

In addition, all subunits of the COP9 signalosome (CSN) complex were present among genes more than 2- and 3-fold upregulated by *sylA* in uninfected plants (Table 4.8). The eight subunits of the CSN show remarkable similarity to the lid subcomplex of the 19S regulatory particle (Wei et al., 1998). This indicates that the CSN has a direct role in protein degradation, possibly as the lid for a specialised CSN proteasome (Schwechheimer and Deng, 2001). Insights have been gained that link the COP9 signalosome closely to the function of the multiprotein ubiquitin ligase (E3) complex, the SCF [Skp/Cullin/F-box] complex (Lyapina et al., 2001; Schwechheimer and Deng, 2001).

Moreover, the RAR1 protein (Table 8.3, At5g51700, row #1145), which functions downstream of multiple R-gene-mediated resistance pathways, was upregulated by *sylA* in uninfected plant tissue. In plants, SGT1, a positive regulator of E3 ubiquitin ligase complexes, has been found to interact with RAR1 (Azevedo et al., 2002; Liu et al., 2002). Therefore, it is possible that RAR1 cooperates with SGT1 to target negative regulators of disease resistance for degradation. A model for involvement of the CSN, RAR1, the SCF ubiquitin ligase complex, and the 26S proteasome in disease resistance is shown in figure 5.2.

Figure 5.2 Model of regulated protein degradation and its function in disease resistance

RAR1 cooperates with SGT1 that is associated with components of the SCF ubiquitin ligase complex to target negative regulators of disease resistance. The SCF complex is regulated by CSN to promote ubiquitination of target proteins. Degradation of target proteins occurs by the 26S proteasome in which the COP9 signalosome replaces the lid (modified after Serino and Deng, 2003).

Since the Arabidopsis genome encompasses about 700 F-box proteins, variable components of the SCF complex, the CSN has the potential to control many E3 ubiquitin ligases and thereby their mediated processes (Gagne et al., 2002). The finding that syringolin alters the abundance of many transcripts encoding F-box proteins (Table 8.3, rows #557ff, 611ff, 620ff) could indicate that syringolin induces selective protein degradation via the CSN.

In conclusion, our results indicate that one crucial effect exerted by syringolin appears to enhance protein degradation which directly or indirectly might allow the plant to influence the presence of key components of disease resistance in plants.

5.3.2 Chaperones

Syringolin application on infected and uninfected plants provoked accumulation of several transcripts encoding heat shock proteins (Hsps). This encompassed members of the five major families of Hsps: Hsp70, the chaperonins (GroEL and Hsp60), the Hsp90, the Hsp 100, and the low molecular weight small Hsps (Table 4.9). Studies of the protective ability of Hsps have focused on their role as chaperones to prevent misfolding of proteins. Hsps/chaperones are known to be expressed in plants not only during high temperature stress but also in response to a wide range of other environmental insults. Most likely, Hsps/chaperones play a crucial role in the re-establishment of cellular homeostasis (Boston et al., 1996; Vierling, 1991). In *Arabidopsis*, six members of the Hsp90 family have been isolated ranging from 80 to 90 kDa (Takahashi et al., 1992; Yabe et al., 1994). The expression of two genes encoding *Hsp81-1/Hsp90.1* and *Hsp81-2/Hsp90.2* (Table 4.9, At5g52640, At5g56030, rows #9, 10) was upregulated by sylA. It was shown that heat shock had a greater effect on the expression level of *Hsp81-1/Hsp90.1* than on those of *Hsp81-2/Hsp90.2* (Takahashi et al., 1992). This corresponds to expression patterns obtained after sylA treatment. Syringolin application on infected plants enhanced the expression of *Hsp81-1/Hsp90.1* already 2-4 fold (t/c ratio: 2,5) and even more when sylA was sprayed on uninfected plants (t/c ratio: 52,1). Interestingly, HSP81-1/HSP90.1 is required for full R-gene mediated resistance against *Pseudomonas syringae* pv. *tomato* DC3000 carrying the avirulence gene *avrRpt* (Takahashi et al., 2003). In addition, accumulation of RPM1 (Resistance to *P. syringae* pv. *maculicola*), conferring resistance against *Pseudomonas syringae* strains that carry the avirulence genes *avrB* and *avrRpm1*, is greatly diminished in specific *hsp81-2/hsp90.2* missense mutants (Hubert et al., 2003). In general, HSP90

proteins may determine whether NBS-LRR proteins are functional in disease resistance by transiently binding of non-native proteins to assist its proper folding (Sangster and Queitsch, 2005; Young et al., 2001). In this context, it was speculated that RAR1 might act as a co-chaperone protecting HSP90-associated NBS-LRR proteins from SGT1b mediated degradation (Holt et al., 2005).

A high number of Hsps transcriptionally induced after sylA treatment was present in the group of the Hsp70 chaperones. Upregulation of Hsp70 genes positively correlated with the acquisition of thermo-tolerance (Lee and Schoffl, 1996). Moreover, Hsp70 proteins were found to interact with signalling molecules including cell-death regulators, thereby negatively affecting the mitochondrial pathway of apoptosis (Beere, 2004, 2005). Interestingly, transcripts encoding mitochondrial Hsp70 and the mitochondrial co-chaperone GrpE were also accumulating after sylA application (Table 4.9, At4g37910, At5g55200, rows #7, 8).

In Arabidopsis, 13 different small Hsps are grouped into five classes in accordance with their molecular phylogeny and localisation in the cell (Vierling, 1991). We detected strong induction of genes encoding small Hsps. The majority belonged to cytosolic class I and II small Hsps (Table 4.9, row #13ff), but highest transcript abundance was found for a gene encoding the mitochondrial *Hsp23.5* (Table 4.9, At5g51440, row #19). This gene exhibited highest expression ratios in infected tissue already 2-4 hat and its expression was enhanced 8-12 hat in infected and uninfected plants. Expression of the gene *Hsp23.6*, encoding a mitochondrial small Hsp (Table 4.9, At4g25200, row #20), was also already more than 2-fold enhanced 2-4 hours after sylA treatment. Since the capability of mitochondria to tolerate heat has a great impact on the whole cell activity and survival, it has been suggested that mitochondrial small Hsps play a major role in the heat tolerance of

plant mitochondria (Sanmiya et al., 2004). In this context, mitochondrial small Hsps of maize were shown to improve mitochondrial electron transport, mainly by protection of the NADH:ubiquinone oxireductase activity of complex I (Downs and Heckathorn, 1998; Hamilton and Heckathorn, 2001). Therefore, a protective role for mitochondrial small Hsps during syngA-dependent stress responses might exist.

Surprisingly, three small Hsps localised in the plastids were transcriptionally downregulated in syngolin-treated plants (Table 4.9, rows #2, 21, 22). Plastid small Hsps protect photosynthetic electron transport during heat stress (Heckathorn et al., 1998). Recently, Zou and co-workers (2005) have shown that destruction of PSII proteins lead to photooxidation of molecules in the PSII which results in ROS (Reactive Oxygen Species) formation and a decrease of photosynthetic activity. In this context, it is conspicuous that syngolin was found to exert strong inhibitory effect on photosynthetic gene expression such as genes encoding chlorophyll a/b binding proteins and components of photosystem I and II (Table 8.3, rows #422ff). This might indicate that chloroplast integrity was negatively affected by syngolin but in contrast to mitochondria, the expression of protective genes was inhibited.

The transcription of Hsp-encoding genes is controlled by regulatory proteins called heat shock transcription factors (Hsfs). The Arabidopsis genome contains 21 genes encoding Hsfs distributed to Hsf-classes A, B, and C (Nover et al., 2001). In contrast to class A Hsfs of plants, a considerable number of Hsfs assigned to classes B and C have evidently no function as transcription activators during heat stress (Baniwal et al., 2004). Syngolin predominantly induced the expression of Hsfs genes belonging to class A (Table 4.10, rows #30ff). In infected tissue syngolin exclusively enhanced transcript abundance of *HsfA2* (Table 4.10, At2g26150, row #31) that, in addition, exhibited highest induction values in uninfected plants treated

with syla. HSFA2 is exclusively found after heat shock induction in complexes (heat shock granules) which are mainly formed by the cytosolic small Hsps and Hsp70 influencing its activity and intracellular distribution (Baniwal et al., 2004). Moreover, synthesis of HSFA2 seems to be strictly heat stress dependent, especially in periods of repeated heat stress and recovery (Nover et al., 2001).

These results imply that heat shock proteins and transcription factors play an important role in plant response to syla, perhaps by directly supporting recovery from stress induced by syla, thus preventing cell damage and cell death.

5.3.3 Mitochondria

Mitochondria are the energy factories of the cells producing ATP molecules, the energy supply for the processes of life. Remarkably, a considerable number of genes upregulated by syla in infected and uninfected plants encodes proteins located in mitochondria.

Since most of the mitochondrial proteins are synthesised in the cytosol, the import of proteins into mitochondria is achieved by a number of oligomeric protein complexes. A single translocase of the outer membrane (TOM) contains the receptors to target proteins that are subsequently passed to two translocases of the inner membrane (TIM) (Koehler, 2004). Two Arabidopsis homologs of these import components were transcriptionally induced by syringolin, namely TIM17 and TOM20 (Table 8.3, At1g20350, At5g40930, row #1660, 1661). In addition, transcriptional upregulation was found for proteases responsible for a rapid breakdown of mitochondrial targeting pre-sequences. This included FtsH (Table 8.3, At1g06430, At1g07510, rows #537f), Clp (Table 8.3, At5g51070, row #541), DegP (Table 8.3, At3g03380, row #556) and Lon proteases (Table 8.3, At5g26860, At3g05790, rows #571f).

Next to several members of the mitochondrial substrate carrier family (Table 8.3, rows #1662ff), transcriptional upregulation was found for a gene encoding a porin family protein located at the outer mitochondrial membrane (Table 8.3, At1g50400, row #1621). The feature of voltage gating porins has been used to name the family of these proteins, the voltage-dependent anion channel (VDAC) family. VDAC, along with the adenine nucleotide translocator, cyclophilin D, and other proteins form a complex called permeability transition pore complex (PTPC) (Crompton et al., 2002). Pro- and anti-apoptotic factors of the Bcl-2 family proteins are thought to be involved in regulating the function of the PTPC (Shimizu et al., 1999; Shimizu et al., 2000). In addition, an increase of VDAC channels can result in closing of the VDAC, thereby suppressing ATP release from the mitochondria in the cytosol (Lemeshko, 2002; Lemeshko and Lemeshko, 2004). Since VDAC closure also affects cytochrome c release in the cytosol, one might speculate that this could directly counteract the induction of cell death.

Among further transcripts encoding mitochondrial proteins that accumulated upon *sylA* treatment we identified a putative prohibitin (Table 8.3, At3g27280, row #547). Since prohibitin is localised at the inner mitochondrial membrane, it is speculated to have impact on mitochondrial membrane potential and ATP production (McClung et al., 1995). Prohibitins have anti-proliferation activity, are ubiquitously expressed, and appear to be essential for cell survival. Based on sequence and structural similarities, prohibitin together with stomatin and a subgroup of HIR- (Hypersensitive Induced Reaction) plant defence-related proteins belong to a superfamily of plant proteins named PID (Proliferation, Ion, and Death) also designated as 'band 7' proteins which may be involved in signalling and regulation of PCD via modulation of ion channel activity (Nadimpalli et al., 2000). Transcripts

encoding representatives of band 7 family proteins such as a stomatin-like protein and several HIR-proteins accumulated in sylA-treated tissue (Table 8.3, rows #546ff).

Oxidative phosphorylation is the process by which cells obtain energy (ATP) when oxygen is present in the cell. Structural basis for oxidative phosphorylation in mitochondria are five protein complexes I-V located at the inner mitochondrial membrane. Syringolin appears to activate a plant-specific bypass of the classic respiratory chain by enhancing transcript abundance of genes encoding rotenone-insensitive NADH dehydrogenases and subunits of the alternative oxidase (AOX). Alternative oxidase, which appears to play an antioxidant role in plant mitochondria, is encoded by five genes in Arabidopsis, four *Aox1* types and one *Aox2* type (Considine et al., 2002). Transcriptional upregulation of *Aox1a*, which is the predominantly expressed isoform, and *Aox1b* (Table 4.6, At3g22370, At3g22360, rows #1, 2) was found in plants treated with sylA. An unexpected change in gene expression was the relatively high level of *Aox1d* transcripts (Table 4.6, At1g32350, row #3). Previously, *Aox1d* transcript levels had been found to be barely detectable in any tissues (Thirkettle-Watts et al., 2003). However, because *Aox1d* transcript levels were enhanced in phytotron experiments using high light conditions (Fiorani et al., 2005) *Aox1d* expression in sylA-treated plants might reflect a situation of cellular stress response.

Unlike the cytochrome pathway, which is coupled to ATP synthesis, electron transport from ubiquinol to AOX is nonphosphorylating and releases energy as heat, thereby preventing overreduction of the ubiquinol pool and ROS generation. Electron flow of the alternative pathway, starting with the oxidation of NADH by the rotenone-insensitive NADH dehydrogenases via the ubiquinone pool to the AOX, allows the oxidation of NADH by mitochondria to continue. Because less ATP is produced, this

results in a decreasing ATP/ADP ratio. Seven types of the rotenone-insensitive NAD(P)H dehydrogenase (ND) identified in the Arabidopsis genome were grouped into three families A, B, and C. Genes encoding NDA1 and NDB2 enzymes exhibited enhanced expression ratios upon sylA treatment (Table 4.6, At2g20800, At1g07180, rows #7, 8).

Interestingly, co-expression of *Aox1a* and *Ndb2* was observed under various cellular stress conditions. Clifton and co-workers (2005) suggested that both AOX1a and NDB2 are capable of forming a functionally alternative respiratory chain allowing oxidation of cytosolic NAD(P)H which is uncoupled from oxidative phosphorylation (Figure 5.3).

Figure 5.3 Diagrammatic representation of the plant mitochondrial electron transport chain

The multi subunit complexes I, II, III, IV, and cytochrome c, which comprise the cytochrome electron transport chain, are shown in white. The stress inducible alternative external NADH dehydrogenase (NDB) and alternative oxidase (AOX1a) are shown in black. The flow of electrons is indicated by arrows with the proposed stress inducible pathway indicated by solid arrows. IMS = intermembrane space, IMM = inner mitochondrial membrane, UQ = ubiquinone (modified after Clifton et al., 2005).

In general, the alternative mitochondrial pathway decreases ROS formation when mitochondria are overflowed with reducing substrate. In this way, activation of the alternative bypass by syringolin would counteract a high reduction state of the ubiquinone (UQ) pool which may result from high NAD(P)H supply and/or the inhibition/dysfunction of the cytochrome pathway (Maxwell et al., 1999; Millenaar and

Lambers, 2003; Moore et al., 2002). The activation of alternative pathways results in decreasing cellular ATP yield which in turn might induce increased glycolytic and TCA cycle turnover to produce reducing substrates such as NAD(P)H. Indeed, a number of genes encoding proteins responsible for sucrose breakdown and glycolytic enzymes were upregulated by syringolin, suggesting that glycolytic activity was enhanced (Table 4.5). In general, this allows effective balancing of cellular NAD(P)H/NAD(P)⁺ and ATP/ADP ratios, thus linking respiratory energy coupling with demands for carbon skeletons (Gray et al., 2004). However, in the case of a restricted cytochrome pathway, stimulation of glycolytic activities would rather overflow mitochondria with reductive substrates, which in turn would stimulate the activity of alternative pathways. As detailed below, a number of transcripts encoding fermentative enzymes were also strongly accumulating.

5.3.4 Metabolic changes

If mitochondrial membrane permeability and ATP supply by oxidative phosphorylation are indeed affected by syringolin one may expect significant effects on bioenergetics and cellular metabolism. Indeed, syringolin leads to considerable transcriptional changes of a high number of genes encoding proteins involved in various metabolic processes. Unexpectedly, transcript abundance of the majority of these genes was lowered by syringolin as represented in figure 4.10. Concerning carbohydrate metabolism, upregulated transcription was exclusively found for enzymes functioning in sucrose break-down, glycolysis, as well as ethanolic and lactate fermentation (Table 4.5).

Strong transcriptional induction of the *pyruvate decarboxylase 1* gene (Table 4.5, At4g33070, row #26) was indicative for the induction of fermentative catabolic activity. Fermentation is the metabolic breakdown of glucose without net oxidation, allowing for the maintenance of ATP generation by glycolysis under anerobic conditions. Since the pathway from pyruvate to acetaldehyde and ethanol involves the activities of pyruvate decarboxylase (PDC) and alcohol dehydrogenase (ADH), it was striking that transcript abundance of the gene encoding the corresponding ADH1 protein was not enhanced by *sylA*. This might be explained by the findings that normal levels of *Adh1* expression were shown to be critical for plant survival under low oxygen conditions and that increased expression of ADH did not affect hypoxia tolerance (Dolferus et al., 2003; Ismond et al., 2003). Moreover, PDC was found to be the main regulatory enzyme in this pathway (Kürsteiner et al., 2003).

In Arabidopsis, four genes encode PDC proteins. Among them, *Pdc1* is the main anaerobically induced gene whereas *Pdc2* is constitutively expressed at low levels (Ismond et al., 2003). In addition, the onset of cellular fermentation in *sylA*-treated cells was emphasised by transcriptional induction of the *Ldh1* (*lactate dehydrogenase 1*) gene (Table 4.5, At4g17260, row #25) encoding an enzyme which catalyses the lactate fermentation pathway from pyruvate to lactate.

High glucose levels stimulate glycolysis. If the increasing glycolytic rate exceeds that of the glycolytic enzyme pyruvate dehydrogenase, responsible for metabolising pyruvate to acetyl-CoA, the activity of PDC directing carbon flow via ethanolic fermentation can be stimulated (Gass et al., 2005). Furthermore, pyruvate is a strong activator of AOX as shown in both soybean (Day et al., 1994; Millar et al., 1993) and tobacco (Vanlerberghe et al., 1995). In this way, electron transport to AOX might help support high rates of carbon flow and helps to modulate pyruvate levels when electron flux through the Cyt pathway is saturated or limited (Vanlerberghe et al., 1995).

However, induction of genes encoding AOX in sylA-treated plants seems not to prevent the engagement of these fermentative activities by the accumulation of pyruvate.

The fact that *Pdc1* overexpression improves low oxygen stress survival only when sugar supply is adequate explains why sugar availability strongly enhances anoxia tolerance (Vartapetian and Jackson, 1997). Interestingly, we observed transcriptional induction of sucrose degrading enzymes by sylA (Table 4.5, rows #2ff). These findings suggest that syringolin application may reflect a physiological situation similar to hypoxia.

This is supported by the observation that syringolin enhanced transcript abundance of a gene encoding a class 1 nonsymbiotic hemoglobin (Table 8.3, At2g16060, row #1195). Overexpression of the class 1 hemoglobin gene, *Glb1* from *Lotus japonica* in potato tubers leads to the formation of hypertrophic lenticels and to higher internal oxygen concentrations in growing tissue (Geigenberger, 2003) indicating that GLB1 might directly interact with a cellular oxygen sensing system.

To test the correspondence between syringolin and anoxia-related gene expression, publicly available microarray data obtained from six-day-old seedlings of *Arabidopsis thaliana* (ecotype Columbia *glabra*) treated under anoxia for six hours (Loreti et al., 2005) were compared to expression patterns obtained in sylA-treated plants. Similar statistical filtering criteria for relevant genes were used in both experiments. A detailed overview of statistical parameters applied to both experiments is given in table 8.7 (Appendix G).

In accordance with sylA-experiments, in anoxic plants the expression of more genes was repressed than enhanced (135 genes \geq 2-fold upregulated, 344 genes \geq 2-fold downregulated). This might result from decreasing ATP availability and was reflected by an inhibition of various metabolic processes in both systems. Of the 5339 genes whose expression was altered more than 2-fold by syringolin in

uninfected plants 8-12 hat (Student's t-test, no MTC), transcript abundance of 148 genes was similarly altered more than 2-fold in plants exposed to anoxia.

A strong overlap of more than 2-fold differentially expressed genes was found for transcripts encoding auxin-responsive proteins whose expression was dramatically repressed under oxygen deprivation and syringolin treatment, respectively. Moreover, this also encompassed several members of the cytosolic small Hsp family, suggesting that Hsps which were hypothesised to support recovery from stress induced by sylA might similarly play a role in survival at low oxygen concentrations.

In addition, transcripts of the *Pdc1* gene that strongly accumulated in sylA-treated plants (Table 4.5, At4g33070, row #26), also exhibited dramatic increase in abundance in plants exposed to anoxia. Therefore, these data support the hypothesis that syringolin indeed triggers an anoxia-like response.

Fermentative activities are responsible for the synthesis of acetaldehyde, ethanol, and lactate that may be toxic to plants, leading to a slow death process, despite plants being in external aerobic conditions (Gaston et al., 2002). In line with that, syringolin application dramatically enhanced the expression of a gene encoding glutamate decarboxylase 1 (Table 8.3, At5g17330, row #172), a Ca^{2+} /calmodulin-dependent enzyme that converts glutamate to GABA (γ -aminobutyric acid) which has been proposed to play a role in counteracting cytosolic acidification during anoxia (Gout et al., 2001) and is essential for the restriction of ROS levels in plants (Bouche et al., 2003).

In summary, genes transcriptionally preventing damage or facilitating recovery to maintain cell survival were induced by syringolin. As detailed above, this encompassed a number of transcripts encoding enzymes of the alternative mitochondrial electron pathway that allow maintenance of NAD(P)H oxidation and decrease in ROI formation as well as enzymes involved in fermentation. In addition,

the accumulation of transcripts encoding heat shock proteins/chaperones may increase the capability to disaggregate, refold, and renature misfolded proteins and offset the otherwise fatal consequences of damaging stimuli. Moreover, transcriptional induction of prohibitin, exhibiting anti-apoptotic activities, might also contribute to promote cell survival.

5.3.5 Transport and detoxification

Several cellular transport-processes appeared to be strongly inhibited by *sylA* as indicated by a high number of respective genes whose expression was downregulated (Figure 4.13). Repression of lipid, sugar, amino acid, and oligopeptide transport might directly correlate with an inhibition of various metabolic processes by *sylA* as described above.

Surprisingly, syringolin seems to inhibit water efflux, reflected by decreased expression of several genes encoding major intrinsic proteins (MIP), such as aquaporines, which are localised at the vacuolar membrane (TIPs, Tonoplast Intrinsic Proteins) and the plasma membrane (PIPs, Plasma membrane Intrinsic Proteins, Table 8.3, rows #1772ff). An inhibition of water channel activity in roots was described as a result from a drop in cytosolic pH associated with low-oxygen stress (Tournaire-Roux et al., 2003). One may speculate that *sylA*-dependent repression of genes encoding proteins involved in water transport activities represents a consequence of acidification caused by accumulating fermentation products such as acetaldehyde, ethanol, and lactate. In addition, downregulation of genes encoding plasma membrane intrinsic proteins (PIPs) hints at a mechanism that minimises water flow through cell membranes, which in turn might counteract further loss of turgor during drought stress.

SylA application lead to increased transcript levels of genes generally associated with detoxification. This included members of the MATE (Multidrug And Toxic compound Extrusion) and ABC (ATP-Binding Cassette) transporter families as well as glutathione-S-transferases (Figure 4.13 and 4.15, Table 8.3, rows #1565ff, 1646ff, 1898ff). ABC-transporters catalyse the efflux of drugs by utilising the energy released upon the hydrolysis of ATP.

Moreover, syringolin increased transcript abundance of genes encoding members of the syntaxin family. Syntaxins are components of vesicle-trafficking. Among them, SYP121 (Table 8.3, At3g11820, row #1769) was postulated to have a function during pathogen-defence, such as the production of large vesicles at infection sites that stain positively for hydrogen peroxide and were implicated to have a function in cell wall strengthening, defence signalling, and antimicrobial activity (Collins et al., 2003). SYP122 (Table 8.3, At3g52400, row #1770) is involved in defence against a broad range of bacterial, viral, and fungal pathogens (Assaad et al., 2004) and is phosphorylated in response to the bacterial elicitor flagellin (Nuhse et al., 2003). Accordingly, it is likely that upregulation of SYP122 and possibly other components of the membrane trafficking machinery by syringolin could play a role in diffuse secretion.

In summary, the functional group of transport-related proteins encompassed a high number of putative detoxifying and secretory proteins whose corresponding transcripts accumulated upon sylA treatment. This may indicate that activities related to cellular detoxification were enhanced in sylA-treated cells. However, it has to be mentioned that ABC transporters are also involved in various cellular processes such as plant growth and development (Martinoia et al., 2002).

5.3.6 Hormones

Syringolin application enhanced transcript abundance of ABA (abscisic acid)-responsive genes (Table 8.3, rows #951f) and a gene involved in ABA biosynthesis (Table 8.3, At1g16540, row #953). Furthermore, one gene that exhibited high transcript abundance encoded the ABI3-interacting protein 2, a member of the zinc-finger transcription factor family (Table 8.3, At5g20910, row #604). Mutation in *Abi3* causes ABA insensitivity (Koornneef et al., 1984). In contrast, syringolin also induced the expression of *Era1* (Table 8.3, At5g40280, row #954), encoding a negative regulator of the ABA-response during germination (Cutler et al., 1996). However, upregulation of *Era1* (*Enhanced response to ABA 1*) might occur in the context of negative feedback tuning ABA signalling. Yet, *sylA*-dependent downregulation of the *Fry1* (*Fiery 1*) gene (Table 8.3, At5g63980, row #956), encoding an inositol polyphosphate 1-phosphatase, favours a role of *sylA* in stimulating ABA-responses, because mutation of the *Fry1* gene has been found to dramatically enhance the expression of ABA- and stress responsive genes (Xiong et al., 2001).

In general, ABA enhances seed dormancy and is involved in drought stress response regulating transpiration by reducing water loss via rapid induction of stomata closure (Buchanan et al., 2001). As detailed above, syringolin reduced transcript accumulation of genes encoding aquaporines indicative for cellular drought stress. In addition, syringolin exerted a dramatic inhibitory effect on cell wall modifying genes (Table 8.3, rows #59ff), which might result from reduced cellular turgor pressure during water deficiency which is important for cell extension. Accordingly, it can be speculated that ABA-responsive gene expression was enhanced due to cellular drought stress which might be stimulated in *sylA*-treated cells.

Surprisingly, the expression of a high number of auxin-responsive genes was downregulated by syringolin (Figure 4.14, Table 8.3, rows #904ff). As noted before, similar negative effects on auxin-related gene expression were also found during anoxia. It has been suggested that either auxin level or signalling is altered by anoxia (Loreti et al., 2005). In addition, it was found that H₂O₂ can negatively regulate the auxin response (Kovtun et al., 2000).

Syringolin application also alters the transcript abundance of genes involved in ethylene-signalling. The expression of genes encoding members of the ERF (Ethylene Response Factor) transcription factor family increased and decreased by approximately equal numbers after syringolin treatment (Table 8.3, rows #963ff, 972ff, Figure 4.14) which gives only weak information of *sylA*-dependent interference with ethylene signalling. However, syringolin was found to induce the expression of *Ein4* encoding an ethylene receptor (Table 8.3, At3g04580, row #960).

Only few genes involved in the jasmonate hormone response exhibited responsiveness towards syringolin (Figure 4.14). The expression of the *Lox1* gene, encoding lipoxygenase 1 (Table 8.3, At1g55020, row #981), which is involved in jasmonic acid biosynthesis, was upregulated by *sylA*, whereas transcript abundance of the *Lox2* gene (Table 8.3, At3g45140, row #985) was lowered by *sylA*. These findings correspond to results obtained in senescencing *Arabidopsis* leaves (He et al., 2002). However, the expression of more genes encoding senescence-associated proteins was downregulated by syringolin (Table 8.3, rows #1806f and 1841ff), indicating that *sylA* may rather counteract senescence.

To conclude, it remains an open question whether ABA is an integral part of the syringolin action or whether regulatory factors involved in ABA-signalling were upregulated due to secondary effects exerted by *sylA*. Furthermore, syringolin exerted

dramatic repressive effect on auxin-related gene expression whereas the accumulation of distinct transcripts indicates the induction of ethylene-signalling. Finally, a role for jasmonate as a part of the syringolin response could not be defined.

5.3.7 Transcription factors

Genes encoding transcription factors (TFs) whose expression was altered by *sylA* included several major families. While transcripts encoding basic helix-loop-helix and Myb TFs were predominantly downregulated by *sylA* (Table 8.3, rows #1373ff, #1456ff), bZIP, HSF, NAM and WRKY TF transcripts increased in abundance (Table 8.3, rows #1247ff, 1266ff, 1283ff, 1324ff and figure 4.12).

A further group of TFs is formed by the DREB (Drought Responsive Element Binding) TF family. Members belonging to the subfamily A-2 of the DREB TF family, which are involved in drought and salt stress tolerance (Liu et al., 1998), were transcriptionally upregulated by *sylA* (Table 4.10, rows #1ff), one of them dramatically in both infected and uninfected plants (Table 4.10, At2g38340, row #1). In contrast, several members of subfamilies A4 to A6 of the DREB TF family that so far have not been implicated in drought tolerance were downregulated by *sylA* (Table 4.10, rows #6ff).

The complexity of plant drought response is represented by the existence of four transcriptional regulatory systems, of which two are ABA-independent and two are ABA-dependent (Shinozaki and Yamaguchi-Shinozaki, 2000). Members of the DREB A2 family function in the ABA-independent drought response, however, crosstalk between these pathways has been suggested (Narusaka et al., 2003).

Interestingly, transcriptional responsiveness of several TF genes involved in drought stress tolerance, together with enhanced transcript abundance of genes encoding proteins involved in ABA signalling as well as transcriptional repression of

water channel proteins suggests that in *Arabidopsis*, syringolin indeed triggers a drought stress response.

A second group of genes encoding transcription factors is formed by the NAM (No Apical Meristem) protein family. The expression of the majority of NAM TF genes was enhanced by *sylA*. NAM TFs are involved in plant development and morphogenesis (Souer et al., 1996). Moreover, members of the superfamily of NAC (petunia NAM and *Arabidopsis* ATAF1, ATAF2, and CUC2) proteins, to which NAM proteins belong, share a conserved role in hormone control and defence responses (Collinge and Boller, 2001), and NAC proteins were postulated to improve resistance against drought stress, as some of them exhibit ABA-responsiveness (Fujita et al., 2004). Thus, NAM proteins may also contribute to improve dehydration tolerance that seems to be triggered by syringolin in *Arabidopsis*. Global alteration of transcript abundance of *Arabidopsis* genes can be examined using the Genevestigator database which collects hundreds of microarray expression data sets. The Genevestigator database can be retrieved from www.genevestigator.ethz.ch (Zimmermann et al., 2004). This revealed that the gene encoding the NAM transcription factor ANAC094, which exhibited strongest expression upon *sylA* treatment (Table 4.10, At5g39820, row #26), was not enhanced by drought stress but strongly inducible by ozone. Since the toxicity of ozone is linked with an increase of reactive oxygen species (Sharma and Davis, 1994) it is tempting to speculate that the expression of *ANAC094* was enhanced by the accumulation of reactive oxygen species (ROS). Accordingly, besides assuming that syringolin lead to cellular drought stress in *Arabidopsis*, these results suggest that syringolin might also trigger ROS accumulation and oxidative stress.

Further proteins transcriptionally activated by *sylA* belonged to the family of WRKY TF proteins. Members of this family (74 in *Arabidopsis*) have diverse biological functions ranging from stress responses to development (Kalde et al., 2003). Interestingly, the two developmental processes in which WRKY transcription

factors were implicated are trichome development and senescence (Johnson et al., 2002; Robatzek and Somssich, 2002).

Wrky6, which was transcriptionally induced by *sylA* (Table 4.10, At1g62300, row #38) exhibited enhanced transcript abundance in senescent leaves as well as in response to infection by pathogenic bacteria (Robatzek and Somssich, 2001). Accordingly, by enhancing transcript abundance of *WRKY6*, syringolin-treated plants might indirectly regulate the expression of a number of leaf senescence-associated genes.

5.3.8 Defence-related proteins

The *Pad4* and *Eds5* genes encoding a triacylglycerol lipase and a homolog of the MATE transporter family, respectively, are functionally involved in the accumulation of salicylic acid during infection with virulent *Pseudomonas syringae* (Glazebrook, 2001; Nawrath et al., 2002). In *Arabidopsis*, PAD4 and EDS5 also play a role in the resistance towards the virulent powdery mildew strain *Erysiphe orontii*, indicating that PAD4 and EDS5 play key roles in defence signalling pathways (Reuber et al., 1998).

Moreover, syringolin induced the expression of two genes encoding CLH1 (chlorophyllase1) and CLH2 (Table 8.3, At1g19670, At5g43860, rows #1149 and 366) responsible for chlorophyll breakdown which was postulated to be correlated with senescence (Tsuchiya et al., 1999). Interestingly, the gene encoding CLH2 was upregulated by *sylA*, indicating chlorophyll degradation and possibly the onset of senescence, whereas CLH1 was transcriptionally repressed by *sylA*. Kariola and co-workers (2005) found that silencing of *Clh1* resulted in reduced lesion formation and was correlated with enhanced pathogen resistance. This was interpreted to be caused by higher ROS-levels resulting from an accumulation of phototoxic

chlorophyll which in turn might strongly enhance SA-dependent defence. These results, together with transcriptional induction of PAD4 and EDS5, which are both involved in the accumulation of SA, indicated that effects triggered by syringolin might directly involve SA or SA-related pathways.

Syringolin was also found to downregulate several disease resistance genes (Table 8.3, rows #1151ff), genes encoding phenylalanine ammonia-lyases (Table 8.3, rows #336ff) required for flavonoid and isoflavonoid synthesis (Dixon et al., 2002), trypsin-inhibitory proteins (Table 8.3, rows #1172ff), and several pathogenesis-related (PR) proteins (Table 8.3, rows #1162ff). Interestingly, the gene encoding PR-1 was identified as the gene that exhibited strongest induction values one hour after syringolin application on uninfected plants (experiment S1, Table 4.11, At2g14610, row #38). The expression of *Pr-1* decreased 8-12 hours after treatment (experiment S12), enhancing the assumption that syringolin indeed might suppress plant defence.

In summary, the accumulation of transcripts encoding enzymes of the alternative mitochondrial electron pathway may indicate that syringolin affects mitochondrial integrity. In this context, the activation of the alternative mitochondrial pathway could help to counteract a high reduction state of the ubiquinol pool possibly resulting from an inhibition of the cytochrome pathway. Transcripts encoding mitochondrial and cytosolic heat shock proteins that assist to renature misfolded proteins may support recovery from stress induced by syringolin. At the same time, metabolism seems to switch to cellular fermentation. In general, induction of the mitochondrial alternative pathway and cellular fermentation provoke a decreasing cellular ATP/ADP ratio. This can stimulate glycolysis. Interestingly, syringolin application lead to an increase of transcripts encoding enzymes involved in sucrose degradation and glycolysis. Strong transcriptional induction of fermentative and glycolytic enzymes may indicate that syringolin triggers an anoxia-like response in Arabidopsis.

In addition, it appears that syringolin also triggers a drought stress response as reflected by the upregulation of genes related to ABA-signalling and genes encoding members of the DREB transcription factor family functioning in the ABA-independent drought stress response.

We found indications that syringolin induces salicylic acid-dependent pathways. Moreover, we speculate that syringolin-dependent induction of a high number of genes involved in protein degradation may directly allow the plant to influence the presence of key components of disease resistance in plants. However, the expression of many disease resistance genes was downregulated by syringolin, indicating an inhibition of cellular defence. This may likely be a consequence of far reaching inhibition of many biosynthetic processes which occurs during low oxygen metabolism and impaired ATP supply (Geigenberger, 2003).

5.4 Transcriptome analysis of the syl_404 mutant

An EMS-mutant screen for the identification of plants that react insensitively towards syringolin treatment revealed one confirmed mutant, designated syl_404. Sporulation efficiency on syl_404 was significantly enhanced upon syringolin treatment compared to infected and syringolin-treated wild-type plants (Figures 4.22 and 4.23).

Microarray analysis was performed to compare expression patterns in syl_404 and wild-type plants upon syringolin treatment. For five genes, the expression was induced in the wild type but repressed in syl_404 (Table 4.17). At present we can only speculate that downregulation of these genes in syl_404 could favour fungal growth on plants treated with syringolin. The transcription factor WRKY53 (Table 4.17, At4g23810, row #5) was found to be expressed during early events of leaf senescence (Hinderhofer and Zentgraf, 2001). Inhibition of senescence-related *WRKY53* expression in syl_404 indicates that syl_404 plants might be able to counteract senescence-related gene expression.

Inspection of raw values obtained from control- and syringolin-treated syl_404 plants revealed high expression of many genes already without syringolin treatment. As is obvious from figure 4.25 and table 8.6 (Appendix F), many transcripts were present in the category of proteins involved in abiotic and biotic stress tolerance. Interestingly, transcripts of genes encoding proteins related to cellular drought stress, including proteins involved in abscisic acid (ABA)-signalling, which is the major hormone involved in water balance and in the response to dehydration stress, exhibited strong expression already in control-treated syl_404 plants (Table 4.18, rows #1ff, Table 8.6, rows #15ff).

Assuming that enhanced expression of ABA-responsive genes may directly be associated with an accumulation of endogenous ABA, one may speculate that syl_404 plants exhibit elevated ABA levels. Interestingly, enhanced ABA levels correlate with increased susceptibility to pathogens (Mohr and Cahill, 2003; Thaler and Bostock, 2004). With regard to ABA-induced susceptibility, it is worth noting that several fungal pathogens can produce ABA (Crocchi et al., 1991). Current evidence suggests that ABA affects disease resistance mainly negatively by interfering with salicylic acid-based resistance (Audenaert et al., 2002). Assuming that syl_404 plants indeed accumulate high levels of endogenous ABA this could explain why syl_404 plants exhibit increased susceptibility to powdery mildew infection upon syringolin treatment.

The majority of transcripts related to ABA-signalling and dehydration stress revealed similarly high expression in control- and syringolin treated syl_404 plants. In contrast, transcripts of genes encoding members of the small heat shock protein (sHsp) family accumulated stronger in syringolin-treated than in control-treated syl_404 plants and stronger than in wild-type plants (Table 4.18, rows #30ff). Small Hsps were found to protect cells from the detrimental effects such as heat (Lee et al., 1997), desiccation (Wehmeyer et al., 1996), and osmotic stress. Thus, enhanced expression of genes encoding sHsps may promote cell survival in the syl_404 mutant.

As detailed before, we have identified 13 genes exclusively upregulated in infected sylA-treated wild-type plants (IS12). We hypothesised that these transcripts might be linked to the occurrence of HR in infected and sylA-treated tissue which was correlated with a restriction of powdery mildew growth (see chapter 5.2). Interestingly, of these 13 genes only two, At2g34930 and At3g04630 (Table 4.3, rows #1, 3), exhibited m/wt ratios ≥ 2 in control- and syringolin-treated syl_404 plants, respectively.

Since sporulation efficiency of powdery mildew was less restricted in syl_404 compared to wild-type plants upon syringolin treatment, this is compatible with the hypothesis that at least some of the 13 genes may indeed be associated with fungal growth restriction and the occurrence of HR in sylA-treated wild-type plants.

Moreover, we have identified 60 genes downregulated by sylA in uninfected wild-type plants (S12) but upregulated by fungal infection (I60). We hypothesised that the encoded proteins might represent candidates that favour fungal life to varying extent (see chapter 5.2). We investigated whether these genes exhibited high transcript levels in syl_404 plants. While none of the genes revealed high expression in syringolin-treated syl_404 plants, transcripts of 10 genes accumulated to a stronger extent in control-treated syl_404 compared to control-treated wild-type plants. These genes are highlighted in bold in table 8.2 (Appendix C). In addition, two genes whose expression was upregulated by syringolin but downregulated by fungal infection in wild-type plants also exhibited m/wt ratios ≤ 2 in control-treated syl_404 plants (Table 4.4, At1g15180, At5g12110, rows #3, 7), and one gene exhibited a m/wt ratio ≤ 2 in syringolin-treated syl_404 plants, respectively (Table 4.4, At5g08600, row #6). Thus, one may speculate that abundances of these transcripts specific for fungal infection contribute to support powdery mildew reproduction in syl_404.

In summary, transcriptional profiling revealed elevated expression of many stress-responsive genes in syl_404 plants already without syringolin treatment, indicating basal expression of these genes in non-treated syl_404 plants, or, perhaps less likely, induction by control treatment. Members of the small Hsp family that exhibited strong expression in syringolin-treated syl_404 plants may contribute to enhance cell survival, which can directly promote powdery mildew reproduction after

sylA application. In addition, gene expression specific for fungal infection may similarly support powdery mildew reproduction in syl_404 plants.

Beyond this, we hypothesise that elevated abundance of transcripts encoding proteins related to ABA-signalling in syl_404 plants may indicate elevated levels of ABA. Since ABA is a key factor in the suppression of disease resistance, higher ABA levels in syl_404 plants may represent the factor that promotes susceptibility to powdery mildew infection. In general, endogenous ABA levels increase during drought stress. Whether syl_404 plants indeed suffer drought stress is speculative. High abundance of transcripts related to drought stress and ABA-signalling in syl_404 plants without syringolin-treatment may indicate that these genes exhibit increased basal expression. Nevertheless, the finding that syl_404 plants showed slight wilting upon syringolin treatment supports the assumption that syl_404 plants exhibit enhanced sensitivity to drought stress which appears to be triggered by syringolin but was never observable in syringolin-treated wild-type plants. We assume that syl_404 plants exhibit enhanced sensitivity to drought stress which is accompanied by a generally elevated transcript abundance of drought-responsive genes. We can further speculate that higher transcript abundance of these genes was associated with enhanced ABA levels and enhanced susceptibility to powdery mildew infection. Thus, relatively minor drought stress might contribute to increase susceptibility to powdery mildew in syl_404 plants.

5.5 Comparison to microarray data in publicly available databases

5.5.1 *Pseudomonas syringae* and pathogen-associated molecular patterns (PAMPs)

Publicly available microarray data from *Arabidopsis* infected with virulent and avirulent *avrRpm1* carrying strains of *Pseudomonas syringae* pv. *tomato* were compared to transcriptional changes exerted by syLA treatment. Microarray data were obtained from five-week-old seedlings of *Arabidopsis thaliana* (ecotype Columbia). Bacterial infiltrations were performed with 10^{-8} cfu/ml in 10 mM MgCl₂ and data derived from plant material collected 24 hat were compared to expression patterns obtained in experiment S12 where plant material was collected 8-12 h after syLA application. An overview of statistical parameters applied to the experiments and corresponding references are given in table 8.7 (Appendix G). The overlap of genes differentially expressed in *Arabidopsis* after syringolin treatment or infiltration with virulent and avirulent strains of *P. syringae* pv. *tomato* is given in figure 5.4.

Figure 5.4 Overlap between genes more than 2-fold differentially expressed after bacterial infiltration and syringolin treatment

The Venn Diagram represents the distribution of significantly ($p\text{-value} \leq 0.05$, MTC) upregulated (A) and downregulated (B) genes in *Arabidopsis* infiltrated with virulent (*P.s.*) and avirulent (*P.s. avrRpm1*) strains of *P. syringae* pv. *tomato* and in plants upon syringolin treatment (S12).

As shown in figure 5.4., a high number of genes was similarly regulated by syringolin and the virulent bacterial strain (*P.s.*), although fewer genes were found in the overlap between genes differentially expressed by syringolin and the avirulent strain of *P. syringae* pv. *tomato* (*P. s. avrRpm1*).

Genes upregulated by *sylA*, avirulent and virulent strains of *P. syringae* pv. *tomato* encoded proteins belonging to different families of heat shock proteins (Hsps), predominantly members of the small Hsps family and heat shock transcription factors. In addition, this also included genes encoding components of the mitochondrial alternative respiratory chain, such as subunit A of the alternative oxidase (AOX1a) and an alternative NADH dehydrogenase (NDB2). As detailed before, activation of these genes may prevent cellular damage and support recovery from stress induced by *sylA*. Accordingly, it seems that cells challenged with bacteria similarly require enhanced abundance of transcripts encoding proteins with protective functions possibly to counteract cellular stress imposed by bacterial infection.

Moreover, syringolin treatment and infiltration with either avirulent or virulent strains of *P. syringae* negatively affect the expression of photosynthesis-related gene expression. Since downregulation of photosynthesis was similar to that found in *P. syringae*-infected soybean (Zou et al., 2005), it seems likely that transcriptional repression of photosynthetic genes by syringolin represents a bacteria-specific effect which is provoked by syringolin.

The two virulent strains *P. syringae* pv. *tomato* DC3000 and *P. syringae* pv. *maculicola* ES4326 cause water-soaked patches on infected leaves of *Arabidopsis* plants (ecotype Columbia). This is the first sign of disease in a compatible interaction and might result from stimulation of cells to 'leak' nutrients and water into the intercellular space where bacteria live (Katagiri et al., 2002). Remarkably, genes

commonly upregulated in *Arabidopsis* by syringolin (S12) and bacterial infections with either avirulent (*P.s. avrRpm1*) or virulent (*P.s.*) strains of *P. syringae* encompassed genes encoding proteins involved in drought tolerance. This included several genes encoding DREB (Drought Responsive Element Binding) transcription factors. Among downregulated genes several encoded proteins involved in cell extension.

Interestingly, genes exclusively differentially expressed by the virulent bacterial strain and syringolin, respectively, included additional drought-responsive genes. Moreover, transcript abundance of genes encoding subunits of the 26S proteasome were also found to increase to a stronger extent in plants infected with the virulent strain. We hypothesise that protein degradation may provide a mechanism by which virulent bacteria achieve compatibility in *Arabidopsis*.

In summary, it appears that gene expression patterns triggered by syringolin in *Arabidopsis* are similar in certain aspects to transcriptional changes exerted by infiltration with bacterial strains of *P. syringae* pv. *tomato*. The fact that *P. syringae* pv. *tomato* does not produce syringolin indicates that these effects must be induced by other bacterial compounds than syringolin. In addition, syringolin-induced gene expression exhibited stronger similarity to expression patterns triggered by the virulent strain of *P. syringae* pv. *tomato*. Therefore, it is tempting to speculate that syringolin may act as virulence factor in *Arabidopsis*.

Basal resistance is activated by conserved pathogen-associated molecular patterns (PAMPs) such as flagellin (Felix et al., 1999), which are present in most bacteria regardless of their pathogenic potential in plants. Flagellin (flg22) was found to be involved in the induction of non-host resistance (Li et al., 2005; Shimizu et al., 2003) and Avr9-induced race specific resistance (Navarro et al., 2004). To test the similarity between the flg22 response and the effect of syringolin exerted on the transcriptome, gene chip data obtained from plants (ecotype Landsburg erecta) treated for 30-min with a 1 μ M solution of flg22 (Zipfel et al., 2004) were compared to expression patterns obtained in Arabidopsis upon sylA treatment. An overview of statistical parameters applied to the experiments and corresponding references are given in table 8.7 (Appendix G).

As illustrated in figure 5.5, a high proportion of genes more than 2-fold upregulated by flg22 was similarly regulated by syringolin in Arabidopsis. However, in contrast to syringolin treatment, only a small number of genes was downregulated in flg22-treated Arabidopsis.

Figure 5.5 Overlap between genes more than 2-fold differentially expressed by flagellin and syringolin treatment

The Venn Diagram represents the distribution of significantly ($p\text{-value} \leq 0.05$) upregulated (A) and downregulated (B) genes in Arabidopsis by flagellin (flg22) and upon syringolin treatment (S12).

Transcripts whose abundances commonly increased in *Arabidopsis* after syringolin and flg22 treatment included RNAs encoding receptor-like kinases, protein kinases, phosphatases, and proteins involved in calcium signalling. Therefore, it seems likely that similar defence-related pathways may be triggered in both systems. As detailed before, we found indications that syringolin may exhibit virulence activity in *Arabidopsis*. However, these results indicate that syringolin may also act as an elicitor in certain aspects.

5.5.2 Abiotic stress responses

Experimental clustering revealed that expression patterns obtained in syringolin-treated plants exhibit resemblance in certain aspects to expression patterns in *Arabidopsis* (ecotype Columbia) observed upon fumigation with ozone (500ppb) for six hours and cycloheximide (10 μ M) treatment. Cycloheximide is a translational inhibitor whereas ozone was found to trigger the production of reactive oxygen species (ROS) leading to an oxidative burst (Schraudner et al., 1998). In addition, we investigated transcriptional changes in 14-day-old *Arabidopsis* cell cultures (ecotype Landsburg erecta) one hour after heat treatment. Expression patterns were also investigated in *Arabidopsis* protoplasts (ecotype Landsburg erecta) treated with the PCD-inducing mycotoxin Fumonisin (20 mM). RNA was extracted at timepoints where 0%, 20% and 30% of protoplast had died in this experiment. An overview of statistical parameters applied to all experiments and corresponding references are given in table 8.7 (Appendix G).

Expression patterns obtained in plants upon heat stress and treatment with fumonisin exhibited only weak similarity to the expression patterns triggered in plants by syringolin. In contrast, many genes whose transcript levels were altered more than 2-fold by syringolin (S12) were similarly altered in plants treated with cycloheximide and in plants exposed to ozone (Figure 5.6).

Figure 5.6 Overlap between genes more than 2-fold differentially expressed by syringolin, ozone, and cycloheximide.

The Venn Diagram represents the distribution of significantly ($p\text{-value} \leq 0.05$) upregulated (A) and downregulated (B) genes in plants by syringolin (S12), cycloheximide, and exposure to ozone.

Among genes commonly upregulated by ozone and syringolin (Figure 5.6 A), a high number encoded heat shock proteins (Hsps), including several members of the small Hsp family, heat shock transcription factors as well as subunit 1a of the alternative oxidase (AOX1a). The AOX1a and a 23.5 kDa mitochondrial Hsp were similarly transcriptionally upregulated by cycloheximide, ozone and syringolin. The encoded proteins support recovery from stress, predominantly imposed on mitochondria. Accordingly, it seems likely that ozone and cycloheximide affect mitochondrial integrity, similar to the effect exerted by syringolin in *Arabidopsis*.

Transcripts whose abundances were commonly lowered by syringolin, cycloheximide, and ozone (Figure 5.6 B) encompassed various functional groups of genes. Among them, a prominent group included genes encoding proteins involved in photosynthesis, indicating that syringolin, cycloheximide, and exposure to ozone can negatively affect photosynthetic activity in *Arabidopsis*.

5.6 A mutant with enhanced resistance to powdery mildew

Besides screening EMS-mutagenised plants (see chapter 5.4), in a second approach for the identification of mutants that exhibit insensitivity to syringolin, we investigated knock-out mutants harbouring T-DNA insertions in a selection of genes upregulated by syringolin. Unfortunately, none of the T-DNA insertion lines was found to exhibit enhanced sporulation efficiency of powdery mildew after syringolin treatment. Thus, despite strong upregulation of these genes by syringolin, none of them appears to encode a protein involved in the curative effect of syringolin on powdery mildew infected *Arabidopsis thaliana* plants.

However, the line isolated for a T-DNA insertion in the At4g12400 gene (encoding a stress-induced protein) revealed an effect independent of syringolin. The respective mutant line (salk_000794) showed impaired growth of the powdery mildew fungus on control and non-treated leaves. Resistance to *E. cichoracearum* on salk_000794 plants was manifested at a relatively late stage in the infection. Spores germinated on the leaf surface and developed networks of secondary hyphae on both salk_000794 and wild-type plants. However, conidiophore formation was dramatically reduced on salk_000794 plants.

Interestingly, this phenotype was similar to the one observed in powdery mildew infected *Arabidopsis edr1* (*enhanced disease resistance 1*) mutants. The *edr1* mutant displays enhanced resistance to *E. cichoracearum*, but does not constitutively express pathogenesis related genes (Frye and Innes, 1998). These observations suggest that the resistance response in *edr1* and salk_000794 plants affects the fungus primarily after onset of conidiophore formation at day four, indicating that the fungus is stopped at a relatively late stage.

The respective gene (At4g12400) was induced in infected syringolin-treated plants 2-4 hat (IS4) and its expression increased in uninfected tissue 8-12 hat (S12). General transcript levels of At4g12400 were compared in the Genevestigator database (Zimmermann et al., 2004). This revealed transcriptional induction of At4g12400 by different chemical compounds. In addition, transcript abundance was enhanced by heat and upon challenge with *Pseudomonas syringae*. Whether salk_000794 displays resistance to *P. syringae* or whether the encoded protein represents a susceptibility factor for these bacteria remains to be determined. However, transcript abundance of At4g12400 was not enhanced by fungal infection (I60). Therefore, basal expression of At4g12400 seems to be sufficient to promote fungal growth. Alternatively, upregulation of the gene may occur in the course of later infection stages at the onset of sporulation.

Recently, we have isolated a second plant homozygous for an independent T-DNA insertion in the genomic sequence of At4g12400 which exhibits reduced sporulation of powdery mildew. Thus, this supports the assumption that non-functionality of the At4g12400 gene indeed negatively affects powdery mildew reproduction in Arabidopsis.

How non-functionality of the At4g12400 gene enables powdery mildew reproduction is not clear. It is conceivable that the corresponding gene product functions as an inhibitor of a certain resistance gene that now responds to *E. cichoracearum*. The identification of a homologous gene in soybean which is inducible by heat shock (Hernández Torres et al., 1995) let us assume that the At4g12400 encoded protein may similarly be involved in cellular stress responses. Speculating that the At4g12400 encoded protein in Arabidopsis has a function in counteracting cellular stresses, the absence of the protein may provoke excessive cellular stress in the infected plant, which in turn can negatively affect successful reproduction of the biotrophic pathogen.

5.6 Conclusions and outlook

Syringolin A was originally hypothesised to directly or indirectly reprogram colonised host cells to undergo hypersensitive cell death in a compatible interaction (Wäspi et al., 2001). In order to better understand the effect of sylA at the molecular level, the aim of this thesis was to monitor transcriptional changes accompanying the HR triggered by sylA in powdery mildew-infected plants. Microscopic investigations revealed that syringolin inhibits powdery mildew reproduction in both *Arabidopsis* and cereals in a phenotypically similar way. This offered the possibility to investigate transcriptional changes underlying the syringolin response by using the *Arabidopsis* full genome gene chip. Unexpectedly, microarray experiments revealed that in uninfected plants, syringolin changed the expression of more genes than in infected plants, and transcripts accumulating in infected plants also accumulated, to even higher levels, in uninfected plants. These results lead to the hypothesis that the cellular response to syringolin was negatively controlled by powdery mildew infection in colonised and neighbouring cells. Changes in transcript abundance by syringolin specific for infected tissue could be shown for 13 genes. We hypothesise that these genes might be linked to the occurrence of HR, although it is not clear whether this is a cause or a consequence of HR. In addition, these few genes were induced only weakly.

The functional annotation of proteins encoded by sylA-affected transcripts lead to the hypothesis that sylA affects mitochondrial function and oxidative phosphorylation. There is evidence that sylA induces a switch to a fermentative metabolism. Direction of electron flux via cellular fermentation could help to avoid overreduction of the ubiquinone pool. In this context, the induction of genes encoding enzymes of the alternative mitochondrial electron pathway supports the assumption that mitochondria in syringolin-

treated cells indeed are flooded with reductive substrate and that the mitochondrion may represent a target of the syringolin action. If we assume that mitochondrial alternative pathways and cellular fermentation are activated in sylA-treated cells, we expect a decreasing ATP/ADP ratio. Thus, the observed inhibition of metabolic processes and energy consuming defence pathways by syringolin may likely be a consequence of impaired cellular energy supply. We speculate that metabolic changes and the switch to alternative pathways may be achieved and regulated by selective removal of proteins by the activity of the 26S proteasome. Impaired mitochondrial function may directly or indirectly lead to enhanced cellular stress in sylA-treated cells. In this context, the accumulation of transcripts encoding protective proteins may be viewed as a response of the plant to counteract the stress imposed by syringolin. If the assumption holds true that the observed reduced sylA response of powdery mildew-infected tissue may be due to a suppressive effect on gene expression the fungus exerts in colonised and neighbouring cells, then the HR in infected and sylA-treated Arabidopsis could be the result of the pathogen-induced suppression of gene expression that may lead to insufficient production of protective proteins.

Assuming that the mitochondrion may represent a direct target in the syringolin response, future work will focus on the ability of syringolin to directly or indirectly inhibit electron flow via the mitochondrial cytochrome pathway. Therefore, changes in the membrane potential of isolated mitochondria could be monitored as recommended by Yao et al. (2002). Alternatively, respiratory rates could be monitored on isolated mitochondria treated with sylA. In addition, determination of acetaldehyde and ethanol concentrations in syringolin-treated tissue would provide evidence whether products of ethanolic fermentation indeed accumulate upon syringolin treatment.

Another approach for the elucidation of the syringolin response in *Arabidopsis* could focus on the investigation of knock-out mutants harbouring T-DNA insertions in a selection of genes upregulated by syringolin. Investigation of 11 loss-of-function mutants for insensitivity to syringolin, e.g. enhanced sporulation efficiency of powdery mildew after syringolin treatment, revealed no candidate. A mutant harbouring a T-DNA insertion in the *Sti1-like* gene (At4g12400) revealed an effect independently of syringolin, i.e. showed impaired sporulation of the powdery mildew fungus on non-treated leaves. A second mutant line homozygous for an independent T-DNA insertion in the genomic sequence of At4g12400 revealed a similar phenotype, thus supporting the assumption that non-functionality of the *Sti1-like* gene (At4g12400) indeed negatively affects powdery mildew reproduction in *Arabidopsis*. The fungus is only affected at the sporulation stage on the At4g12400 mutant. Sporulation may be particularly stressful for the host plant. Thus, the At4g12400 encoded protein may be necessary to keep colonised cells alive long enough for the fungus to complete its live cycle. Currently, we are investigating whether basal expression of At4g12400 is sufficient to promote fungal growth or whether upregulation of the gene may occur in the course of later infection stages at the onset of sporulation.

An unexpected aspect of the syringolin response is represented by the finding that syringolin also triggers a drought stress response in *Arabidopsis* as reflected by the upregulation of genes related to ABA-signalling and genes encoding proteins involved in the ABA-independent drought response. In this context, it is intriguing that virulent strains of *Pseudomonas syringae* cause water-soaked patches on infected leaves of *Arabidopsis* plants as a visible sign of nutrient and water leakage into the intercellular space. Whether the syringolin triggered drought response may be related to bacteria-induced water leakage observed in *Arabidopsis*

is speculative. In any case, the finding that syringolin-induced gene expression exhibited stronger similarity to expression patterns triggered by the virulent strain of *P. syringae* suggests that syringolin may act as virulence factor in *Arabidopsis*.

Remarkably, the topic of a drought stress response recurred with regard to the phenotype of a mutant with reduced resistance to powdery mildew infection upon syringolin treatment. This mutant revealed enhanced abundance of ABA-related transcripts without syringolin treatment. We hypothesise that this was associated with elevated endogenous ABA-levels in these plants. Because endogenous ABA can suppress disease resistance, this would explain why syl_404 plants exhibit enhanced susceptibility to powdery mildew infection upon syringolin treatment. Unexpectedly, syl_404 mutant plants exhibited slight wilting upon syringolin treatment whereas wilting was never observed in syringolin-treated wild-type plants. Syringolin was found to induce the accumulation of transcripts encoding proteins involved in the ABA-dependent and ABA-independent drought response in wild-type plants. Thus, it is tempting to hypothesise that syringolin indeed triggers a drought stress response in *Arabidopsis*. We further speculate that wilting in syl_404 plants resulted from enhanced sensitivity of these plants to respond to drought stress. In addition, syl_404 plants revealed elevated abundance of many transcripts encoding stress-related proteins. Accordingly, enhanced expression of stress-related genes may help to support cell survival and thus prevent HR in infected syringolin-treated syl_404 plants. This hypothesis is compatible with the scenario developed above, i.e. that a pathogen-induced downregulation of genes encoding stress-related and protective proteins could trigger HR and resistance to powdery mildew in sylA-treated wild-type plants. Identification of the respective gene bearing the mutation by mapping using ecotype-specific PCR-based markers will help to understand the phenotypic and

transcriptional changes in syl_404 plants that underly the reduced resistance to powdery mildew infection upon syringolin treatment.

Thus, HR elicited in infected and sylA-treated plants appears not to depend on specific regulation of certain genes, but might rather represent the result of pleiotrophic effects caused by syringolin treatment and fungal invasion. Another aspect of the syringolin response was represented by the assumption that syringolin may exhibit virulence activity in *Arabidopsis*. It is tempting to speculate that sylA acts as an effector of *P. syringae* pv. *syringae* that helps to put host plant cells into a physiological state from which the bacteria may profit. Intriguingly, a number of effectors secreted by *P. syringae* DC3000, which exhibit virulence activity in *Arabidopsis thaliana*, have been shown to suppress the HR in nonhost plants (Abramovitch et al., 2003; Bretz, et al., 2003; Jamir et al., 2004). Thus, transcriptional changes induced by sylA in *Arabidopsis* could be interpreted in the light of a putative virulence activity exerted by syringolin that may include the suppression of HR. The study of syringolin-negative *P. syringae* pv. *syringae* mutants on a host plant species may help to shed light on this subject.

6 Materials and Methods

6.1 Plant material and fungal strains

Microarray experiments were carried out in the susceptible *Arabidopsis thaliana* ecotype Columbia. EMS mutagenised *Arabidopsis* seeds (Col-0) were purchased from Lehle Seeds (Round Rock, TX, USA). T-DNA insertion lines were obtained from the SIGnAL collection of the Salk Institute for Genomic Analysis Laboratory (Alonso et al., 2003) via the Nottingham *Arabidopsis* Stock Centre, <http://signal.salk.edu>. T-DNA insertion lines were generated in the Columbia and Wassilewskija ecotypes of *Arabidopsis thaliana*.

A culture of a powdery mildew pathogen was isolated from an infected *Arabidopsis thaliana* plant (ecotype Columbia) growing in a climate chamber at the Institute of Plant Biology in Zürich and was used throughout these studies. Database searches of the 16S rRNA sequence revealed that this strain was most closely to the two species *Erysiphe cichoracearum* and *Erysiphe orontii*. Microscopic investigations of culture specific morphological characteristics such as conidiophore foot cells and septation were performed by Prof. R. Honegger and revealed the isolation of a culture of *Erysiphe cichoracearum*.

6.2 Plant and fungal growth conditions

Four to six plants were grown in 5-cm-diameter pots filled with commercial compost (Einheitserde, Type ED 73, Buchenberg, Germany). Pots were covered with plastic wraps to ensure high humidity and were stratified for three days at 4°C before being placed in growth chambers. Plants were grown with a 16 h photoperiod (100-150 $\mu\text{mol m}^{-2} \text{sec}^{-1}$) at 21°C to 22°C and 80-90% relative humidity. Covers were removed after the seeds sprouted and the first leaves were emerging. Adult plants (12-14 days after germination) were used for experimental analysis.

For the reproduction of powdery mildew inoculum, *Arabidopsis thaliana* plants with six to eight leaves (about three to four weeks old) were inoculated weekly. Inoculation of *Arabidopsis* with *Erysiphe cichoracearum* was performed in a wind still chamber. Heavily infected leaves of former infection rounds were slightly dapped on the surface of four to five rosette leaves until the whole leaf surface was covered with spores. After inoculation, plants were again transferred to the growth chambers, covered with a plastic lid for 12 hours, and kept under the conditions given above.

6.3 Infections

6.3.1 Infection of plant material used for gene chip experiments

Leaves of 14-day-old plants used for RNA extraction and hybridisation of ATH1 gene chips were infected with *Erysiphe cichoracearum* by tapping highly sporulating leaves of *Arabidopsis* on the leaf surface of experimental plants. Infection density was quantified by single spore counting and determined to be ~200 spores/mm².

6.3.1.1 Estimation of proportion of powdery mildew-infected cells in Arabidopsis leaves

Microscopic investigations on leaf cross-sections revealed an average number of 6400 mesophyll cells and 160 epidermal cells on the adaxial leaf side per field of view. Estimating a similar number of epidermal cells on the abaxial side, it was calculated that the leaves consist of 95% mesophyll cells (6400 cells/field of view) and of only 5% epidermal cells (2 x 160 cells/field of view). Since the abaxial side remained uninfected in all gene chip experiments, the total number of uninfected cells corresponded to 6560 cells (6400 + 160), resulting in 2,4% adaxial epidermal cells per leaf.

Arabidopsis seedlings were infected at high spore density (~200 spores/mm²) following protocols described above. Eighteen hours after infection, successful interactions, represented by germinated spores forming either appressoria or primary and secondary hyphae, respectively, were determined. This revealed 47 interactions on 160 adaxial epidermal cells per field of view. Accordingly, 29% of all cells on the adaxial leaf side were successfully infected by powdery mildew. Finally, it was calculated that the proportion of infected cells in relation to all cells of the leaf was 0.7% (0.29 x 0.024) on average.

6.3.2 Infection of plant material used for microscopic evaluation

Plant material used for microscopic investigations and for determination of sporulation efficiency of T-DNA insertion lines as well as of EMS-mutagenised plants was infected at ~180 spores/mm². Inoculation was performed with an artist's fine brush to gently dislodge conidia from highly infected leaves to avoid clotting of spores. Infected plants were held approximately two cm above experimental plants to

brush down spores on the primary leaves. Furthermore, slight blowing ensured distribution of spores on the leaf surface. Afterwards, plants were covered for 12 hours and kept under conditions described above.

6.4 Syringolin A isolation

Syringolin A was isolated from still cultures of *Pseudomonas syringae* pv. *syringae* strain B301D-R as described by Wäspi et al. (1999). Three-step purification included partition chromatography on an Amberlite XAD 16 column (2.6x 40 cm; Rohm and Haas, Philadelphia (PA), USA), reversed phase HPLC on a Nucleosil 100 7 C18 250/20 column (Macherey-Nagel, Duren, Germany), and FPLC on a Superdex 30 16/60 gel filtration column (Pharmacia, Uppsala, Sweden; for details see (Wäspi et al., 2001)).

6.5 Syringolin treatment

Syringolin treatment of infected plants was carried out 48 hours after inoculation. Plants were sprayed with distilled water containing 20 µM syringolin and 0,05% (v/v) TWEEN 20 or a control solution (0,05% (v/v) TWEEN 20). Cyprodinil (Novartis AG, Basel, Switzerland) was kindly provided by Dr. M. Oostendrop (Novartis Crop Protection AG, Basel, Switzerland). The substance was dissolved in acetone and diluted with water to a final concentration of 0,05%. The solution was sprayed as described above. Control plants were treated with the solvent only. Plant material was collected at various timepoints after treatment. For microscopic as well as molecular analyses, primary leaves were harvested, exclusively.

6.6 Microscopy

To investigate fungal infection stages by bright field microscopy and to monitor autofluorescence of plant cells, *Arabidopsis* leaves were destained by overnight immersion at room temperature in a 1:2 (v/v) dilution of a lacto-phenol stock solution (phenol : lactic acid : glycerol : water = 1:1:2:1) with ethanol. Fungal structures were stained with coomassie blue (0.6% (w/v)) in ethanol. Leaves were incubated for no longer than one minute in the staining solution and cleared immediately after staining in sterile water. Leaf segments were mounted onto microscopic slides in 40% (v/v) glycerol. Microscopic inspection with an Axioplan microscope (Carl Zeiss AG, Oberkochen, Germany) was done by bright-field or blue light incident fluorescence microscopy (excitation filter 450-490 nm; bypass filter 515-565 nm). Images were captured with the Magna Fire 2.0 digital camera (Optronics, Goleta (CA), USA) using auto exposure settings.

6.7 RNA extraction

Plant material was ground to a fine powder in liquid nitrogen using pestle and mortar. Alternatively, 50-100 mg plant material was homogenised with an electrical homogeniser by totally adding 750 µl of Trizol extraction buffer (Invitrogen BV, Groningen, Netherlands). Subsequently, RNA was extracted according to the manufacturer's protocol (Chomczynski and Sacchi, 1987). The RNA was then further purified using the RNeasy Kit (Qiagen, Basel, Switzerland) according to the protocols of the manufacturer.

6.8 Microarray experiments

6.8.1 Target preparation and hybridisation

The integrity of RNA used for gene chip hybridisation experiments was checked on a bioanalyser (Agilent Technologies, Inc., Palo Alto (CA), USA). For gene chip experiments described in chapter 4.1.2, double stranded cDNA was synthesised with the SuperScript kit (Invitrogen, Basel, Switzerland) using 15-20 µg total RNA as starting material. Purification was done with the Affymetrix GeneChip Cleanup module (Affymetrix, Bucks, UK). The probe was labelled with the Ambion MEGA Script T7 kit (Ambion, Huntingdon, UK) and finally purified again with the Affymetrix GeneChip Sample Cleanup module. Three independent biological replicates were performed for all experiments. For gene chip experiments performed on wild type and mutant *syl_404*, probe preparation was carried out according to the one-cycle target labelling and control reagent package (Affymetrix, Bucks, UK) by Marzanna Künzli-Gontarczyk (Functional Genomics Centre, Zürich). Experiments were repeated in duplicates. After purification of the cRNA, the quality of labelled cRNA was checked on a bioanalyzer (Agilent Technologies, Inc., Palo Alto (CA), USA). Fragmentation of the labelled RNA and chip hybridisation were performed as recommended by Affymetrix (Affymetrix, Bucks, UK). The technical manual was provided by Affymetrix (http://www.affymetrix.com/support/technical/manual/expression_manual.affx).

6.8.2 Data analysis

Raw data were processed with the Affymetrix Microarray Suite 5.0 software package. Data analysis was performed using GeneSpring 7.0 software (Silicon Genetics, Redwood City, CA).

Genes with an “absent” call for the detection value in all replicates of one gene chip experiment were excluded from the list (flag filtering). Furthermore, genes were filtered based on their control strength, representing a value calculated from all normalisations applied to the experiment. In the case of experiments consisting of three biological replicates, the Cross-Gene Error Model (GEM) was activated to determine between-sample variation. Thereby, deviation for each gene signal is based on how its intensities vary across replicate samples. In general, the Cross-Gene Error Model provides a more accurate estimate for the precision of a gene signal by combining measurement variation and between-sample variation information. A variance components analysis is performed using the estimates of measurement variation to estimate standard errors and to compare mean expression levels between experimental conditions. If replicates are available, the variance is calculated on the basis of biological variability (sample variation).

In the absence of visualisation or diagnostic methods (Genespring currently has none), it is safest to assume that variability may differ between treatment and control. This rules out the use of Student’s t-test. The Welch’s t-test corrects for differences in variability. Because we assumed that our data are normally distributed, Welch’s t-test was chosen, although three replicates are not enough to determine normal distribution, it is generally thought to be a reasonably safe assumption. Therefore, differentially expressed genes were identified by computing two-sample Welch’s t-test statistics based on variances calculated by the Cross Gene Error

Model including multiple test correction according to Benjamini and Hochberg (Benjamini and Hochberg, 1995). Genes that exhibited a larger than 2-fold difference in their signal values between control and treatment were extracted.

In the case of few replicates, Genespring software recommends to increase stringency of statistical filtering by assuming that variances of gene expression were equal. Thereby, parameters that had to be determined were reduced by assuming that variances of both samples were equal instead of calculating variances for the two groups. Consequently, for experiments that were based on two replicates, differentially expressed genes were identified by computing Student's t-test including multiple test correction according to Benjamini and Hochberg (Benjamini and Hochberg, 1995).

6.9 Identification of plants homozygous for T-DNA insertions

The majority of T-DNA insertion lines was obtained from the SIGnAL collection of the Salk Institute for Genomic Analysis Laboratory (Alonso et al., 2003) via the Nottingham Arabidopsis Stock Centre. The *Arabidopsis thaliana* NAM-insertion line GABI-Kat 027D08 (At5g39820) was kindly provided by Patrick Schweizer (IPK Gatersleben).

6.9.1 Primers and PCR

DNA was extracted from seedlings of M2 populations of T-DNA insertion lines according to Fulton et al. (1995). For PCR, primers flanking the insertion were used in combination with a primer corresponding to the T-DNA left border to verify plants homozygous for the T-DNA insertion. The oligonucleotides were obtained from Microsynth AG (Balgach, Switzerland) and are listed in table 6.1.

Table 6.1 Primers used for verification of homozygous T-DNA insertions

(5) Gene specific primer forward

(6) Gene specific primer reverse

(*) Plants homozygous for the T-DNA insertion in the gene were kindly provided by Sonia Plaza, Institute of Plant Biology, University of Zurich

PCR was carried out in a 20 µl volume containing 1 µl DNA-template (0,5-1 µg), 2 µl of dNTP mix (1 mM), 0,4 µl of each primer (10 pmol/µl), 2 µl of 10x reaction buffer and 0,2 µl Taq-polymerase (5 units/µl) (Sigma-Aldrich, Buchs SG, Switzerland). The thermocycling conditions were: 94°C 3', [94°C 45'', annealing temperature 45'', 72°C 60''] x 25-30 cycles, 70°C 10'. PCR reactions were mixed with 2 µl gel loading buffer (30% glycerol, 1x TBE, 0,25% bromphenole blue) and were separated on a 1,5% agarose gel.

6.9.2 Sequencing

For sequencing, PCR products obtained with T-DNA left border primer and the respective gene specific primers were purified with GFX spin columns (Amersham Biosciences, Uppsala, Sweden) prior to sequencing. The dideoxy termination method (Sanger et al., 1977) was used for sequencing and sequences were determined using an automated sequencer (ABI377, Applied Biosystems, Foster City, U.S.A.).

6.9.3 Southern blot hybridisation

For southern blots hybridisations, DNA was extracted from leaves of 2-week-old plants according to Fulton et al. (1995). After digestion of the DNA with *Bam*HI, DNA was separated by electrophoresis on a 0.8% agarose gel and let run for four to six hours at 50 V. DNA transfer to a cellulose membrane (HybondTM-N+, Amersham Bioscience, UK) was carried out overnight. The probe was amplified from the pBIN-pROK2 insertion sequence (<http://signal.salk.edu/pBIN-pROK2.txt-new>) by PCR with the primer pairs given in table 6.2 and separated on a low-melting agarose gel. Labelling with ³²P and hybridisation were performed according to Stein et al. (2000).

Table 6.2 Primers used for amplification of the probe sequence

6.9.4 RT-PCR

Total RNA from Arabidopsis leaves was extracted as described in chapter 6.7. The reverse transcription was performed with SuperscriptTM II RNase Reverse Transcriptase kit (Invitrogen, Basel, Switzerland) as follows: 10 µg of RNA were incubated with 1 µl of oligo (dT) (500 µg/ml) and 1 µl of dNTP mix (10 mM) for five minutes at 65°C. The samples were chilled on ice and 4 µl of 5x first-strand buffer, 2 µl DTT (0.1 M) and 1 µl RNase Out (40 units/µl) were added (Invitrogen AG, Basel, Switzerland). The samples were incubated two minutes at 42°C and 1 µl (200 units) of SuperscriptTM II Reverse Transcriptase was added. For reverse transcription, the samples were incubated 90 minutes at 42°C. The reaction was stopped by incubation at 70°C for 15 minutes. Subsequently, the cDNAs were used for regular PCR with gene specific primers.

8 Appendix

Abbreviations

SylA	syringolin A
HR	hypersensitive reaction
ROS	reactive oxygen species
PCD	programmed cell death
<i>E. c.</i>	<i>Erysiphe cichoracearum</i>
<i>Sti</i>	<i>stress-induced</i>
Col	Columbia
Ler	Landsburg erecta
dpi	days post-inoculation
hai	hours after infection
hat	hours after treatment
MTC	multiple test correction
LRR	leucine-rich repeat
SA	salicylic acid
Flg22	flagellin
<i>P. s.</i>	<i>Pseudomonas syringae</i>

Table 8.1 P-values of *sylA*-responsive genes exhibiting higher t/c ratios in infected plants (IS12) compared to uninfected plants (S12)

Description	Protein	Locus ¹	t/c ratio ²		p-value
			IS12	S12	
expressed protein		At5g14730	6,7	3,5	0,02
hypothetical protein		At5g57510	4,3	2,6	0,07
putative glutathione S-transferase	GSTU1	At2g29490	17,8	13,9	0,08
expressed protein		At2g35480	8,4	6,3	0,11
MATE efflux family protein		At1g15180	8,8	4,2	0,13
putative galactinol synthase		At1g60470	2,7	2,1	0,18
expressed protein		At5g06190	7,2	4,7	0,20
putative calcium-dependent protein kinase		At3g56760	2,8	2,6	0,22
expressed protein		At5g11290	15,0	12,5	0,25
lectin-related, low similarity to lectin 3		At2g43730	6,8	5,5	0,25
autophagy 8e		At2g45170	3,6	3,3	0,28
expressed protein	FRL1	At5g16320	2,3	2,2	0,30
putative chromosome-associated kinesin		At5g60930	2,9	2,6	0,32
putative splicing factor		At4g38780	3,9	3,6	0,33
hydroxyproline-rich glycoprotein family protein		At3g45230	2,2	2,1	0,33
putative sugar transporter		At2g48020	3,1	2,9	0,35
expressed protein		At5g23460	2,6	2,5	0,38
expressed protein		At5g64230	7,8	7,6	0,45

- (1) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>).
- (2) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$) and MTC.

APPENDIX C

Table 8.2 T/c ratios of genes downregulated by sylA in uninfected plants (S12) and upregulated by fungal infection alone (I60)

Row	Description	Locus ²	Protein	t/c ratio ³	
				S12	I60
	Functional categories¹				
	Transcription factors				
1	ethylene-responsive element-binding factor 2	At5g47220		0.19	2.65
2	WRKY family transcription factor	At4g01720	WRKY47	0.26	2.89
3	Transport				
4	auxin efflux carrier family protein	At1g76520		0.29	2.12
5	glucose transporter	At1g11260	STP1	0.33	3.19
6	haloacid dehalogenase-like hydrolase family protein	At1g72700		0.38	5.51
7	oligopeptide transporter OPT family protein	At5g64410		0.24	3.58
8	putative metal transporter	At1g05300	ZIP5	0.24	2.22
9	putative metal transporter	At1g55910	ZIP11	0.35	2.10
10	putative UDP-galactose/UDP-glucose transporter	At1g14360		0.37	2.42
11	sodium:solute symporter family protein	At5g45380		0.32	6.82
12	sulfate transporter	At1g78000	Sultr1;2	0.17	2.41
13	UDP-galactose/UDP-glucose transporter	At2g02810		0.43	3.96
14	Response to abiotic and biotic stimuli				
15	auxin-responsive family protein	At3g12830		0.37	2.89
16	beta-1,3-glucanase	At3g57240	BG3	0.30	25.81
17	disease resistance family protein	At2g15080		0.07	4.03
18	disease resistance family protein	At3g23110		0.49	4.02
19	disease resistance response protein-related	At1g55210		0.44	2.70
20	polygalacturonase inhibiting protein 1	At5g06860	PGIP1	0.39	2.34
21	putative 12-oxophytodienoate reductase	At1g17990		0.32	2.65
22	putative 9-cis-epoxycarotenoid dioxygenase	At3g14440	NCED3	0.38	3.04
23	putative anthranilate synthase beta subunit	At5g57890		0.37	2.27
24	receptor-like protein kinase, putative	At3g45860		0.46	10.13
25	seven-transmembrane MLO family protein	At3g45290	MLO3	0.48	5.76
26	Protein metabolism				
27	aspartyl protease family protein	At5g10760		0.18	5.21
28	DNAJ heat shock N-terminal domain-containing protein	At3g13310		0.49	2.12
29	shepherd protein	At4g24190	SHD	0.34	2.45
30	small ubiquitin-like modifier 3 (SUMO)	At5g55170	SUM3	0.44	2.67
31	Kinase activity				
32	leucine-rich repeat family protein	At5g49760		0.40	2.60
33	protein kinase family protein	At4g04540		0.24	3.05
34	protein kinase family protein	At4g23220		0.24	6.31
35	protein kinase family protein	At5g25440		0.29	3.90
36	putative S-receptor protein kinase	At1g65790	ARK1	0.34	2.34
37	putative leucine-rich repeat transmembrane protein kinase	At5g45800		0.27	3.46
38	Hydrolase activity				
39	acid phosphatase type 5	At3g17790	ACP5	0.45	2.28
40	GDSL-motif lipase/hydrolase family protein	At5g03610		0.43	3.26
41	glycosyl hydrolase family 17 protein	At3g13560		0.33	2.51
42	glycosyl hydrolase family 17 protein	At4g34480		0.37	2.61
43	glycosyl hydrolase family 3 protein	At5g20950		0.24	2.20
44	pectinesterase family protein	At4g02330		0.09	2.50
45	pectinesterase family protein	At5g53370		0.29	2.71
46	Biological process unknown				
47	ankyrin repeat family protein	At2g24600		0.28	2.41
48	ankyrin repeat family protein	At5g54610		0.15	3.60
49	C2 domain-containing protein	At3g18370		0.41	2.06
50	calcineurin-like phosphoesterase family protein	At1g13750		0.46	3.34
51	calnexin, putative	At5g07340		0.35	3.17
52	calreticulin 2	At1g09210	CRT2	0.32	3.32
53	expressed protein	At1g74440		0.36	2.02
54	expressed protein	At4g23880		0.35	2.58
55	expressed protein	At4g30500		0.41	2.82
56	expressed protein	At5g19875		0.49	2.35
57	expressed protein	At5g45480		0.39	2.33
58	expressed protein	At5g53110		0.33	3.11
59	expressed protein	At5g52540		0.40	2.50
60	glycosyltransferase family 14 protein	At3g15350		0.44	2.41
61	glycosyltransferase family protein 47	At1g80290		0.39	2.03
62	kelch repeat-containing F-box family protein	At1g80440		0.29	2.73
63	MutT/nudix family protein	At2g01670		0.37	2.39
64	phytochelatin synthetase-related	At5g60950		0.11	4.42
65	protease1 (ppl)-like protein	At2g38860	YLS5	0.36	4.01
66	transferase family protein	At3g50280		0.14	2.02

- (1) Transcripts were grouped according to biological function GO (Gene Ontology) terms.
- (2) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>). In bold: genes that exhibited m/wt ratios ≥ 2 in control-treated syl₄₀₄ plants (data derived from two independent experiments and relevant genes were filtered by the Student's t-test ($p \leq 0.05$)).
- (3) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$) and MTC.

Table 8.3 T/c ratios of genes more than 2-fold differentially expressed in infected sylA-treated plants (IS12) and more than 3-fold differentially expressed in uninfected plants treated with sylA (S12)

- (1) Transcripts were grouped according to biological function GO (Gene Ontology) terms. Genes with unknown biological functions were excluded from table 8.3.

- (2) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>).
- (3) Data derived from three independent experiments. Differentially expressed genes were filtered by the Welch's t-test ($p \leq 0.05$) and MTC.
Grey filling designates t/c ratios ≥ 2 (IS12) and ≥ 3 (S12); no filling designates t/c ratios $\leq 0,5$ (IS12) and $\leq 0,333$ (S12).
- (*) Abbreviations for the extracellular domains of receptor-like protein kinases (RLKs): CrRLK1, *Catharanthus roseus* RLK1; DUF26, domain of unknown function 26; K, kinase; LEC, legume lectin; LRR, leucine-rich repeat; SD, S-locus glycoprotein-like domain; TK, transmembrane/kinase; WAKL, wall-associated kinase like.

Table 8.4 Sporulation efficiency of powdery mildew on syl_404 upon syringolin treatment

M3 population	Experiment No.	Sporulation efficiency [%] ¹		
		weak sporulation	intermediate sporulation	heavy sporulation
wild type	1	44	34	22
	2	88	10	2
syl_404	1	23	29	48
	2	32	27	41

(1) Sporulation efficiency was evaluated according to the scheme presented in table 4.13.

- (1) Transcripts were grouped according to biological function GO (Gene Ontology) terms. Genes with unknown biological functions were excluded from table 8.6.
- (2) The annotation of the genes derived from TAIR, the Arabidopsis Information Resource (<http://arabidopsis.org>).
- (3) Data derived from two independent experiments: m/wt ratios were calculated from the data derived from control-treated syl_404 and wild-type plants. Genes that passed statistical filtering based on Student's t-test ($p \leq 0.05$) are highlighted in bold.
- (4) Data derived from two independent experiments: m/wt ratios were calculated from the data derived from syringolin-treated syl_404 and wild-type plants. Genes that passed statistical filtering based on Student's t-test ($p \leq 0.05$) are highlighted in bold.
- (5) Data derived from two independent experiments. t/c ratios were calculated from data derived from wildtype (wt) and syl_404 plants. Genes that passed statistical filtering based on Student's t-test ($p \leq 0.05$) and MTC are highlighted in bold.

9 Acknowledgements

In the first place, I would like to thank Prof. Dr. Robert Dudler for giving me the opportunity to work in his group. I am very grateful for his support and endless encouragements during difficult periods of work. He greatly assisted me with scientific writing.

I also wish to thank Prof. Dr. Beat Keller for taking charge of the co-referate.

I am much obliged to Andrea Patrignani and Uli Wagner for their help and excellent supervision during long lasting sessions of gene chip hybridisation and data analysis.

I thank Prof. Dr. Felix Keller for his generous help with the HPLC and Prof. Dr. Rosmarie Honegger for specifying the powdery mildew isolate.

The encouragement and support of Beatrice Scherrer have been invaluable to me. Your friendship, simply put, has greatly improved several difficult periods of work and has contributed to feel home in Switzerland.

I am grateful for the assistance, generosity, and advice I received from Barbara Schellenberg. I especially thank you for critically reading the manuscript.

I wish to thank Olaf Abderhalden and Rémy Bruggmann for the warm reception in the group, for their technical support, and for facilitating my first steps in Switzerland.

I would like to thank all the other members of the group, especially Roshani Shakya, Simone Rau and Zsuzsa Hasenkamp.

I extend many thanks to Theres Imhof-Klimm for her generous help, to Nabila Yahiaoui, Susanne Brunner, Silvia Travella, Urs Ochsner and all the other members of the Beat Keller group. In particular, I thank Dani Stutz for solving all my computer problems.

I am especially grateful to my partner Daniel Maring for his love and patience during intensive periods of work. I thank you not only for enduring every emotion and the countless hours of detachment but for believing in me all these years.

Last but far from least, I would like to thank my parents who made my education possible, for their support, and enthusiasm. I wish to thank my sister for listen to all my complaints and for her immense encouragements. They all have made this work possible.

10 Curriculum vitae

Name	Kathrin Michel
Date of birth	May 22, 1976
Place of origin	Mainz, Deutschland
1982-1986	Primary school in Mainz
1986-1995	Secondary school in Mainz
1995-2001	Undergraduate studies at the University of Giessen
March 1999	Practical training at Roche Diagnostics, Mannheim
October 2001	Diploma in biology, University of Giessen
2002-2006	Ph.D. thesis at the Institute of Plant Biology at the University of Zürich
